launch vehicle project, since in early 1973 it was announced that an Indian satellite would go into orbit in the middle of 1974 atop a Soviet rocket launched from within the Soviet Union. This was to be a much heavier payload than the one planned for an Indian launch. Though good progress has been reported from time to time on the satellite part of this latter project, the launch, first postponed to the end of 1974, has now been rescheduled for sometime during 1975. A satellite prototype was reported sometime ago to have undergone successful tests both at Bangalore and in the Soviet Union. The small delay in launching could be because of either or both of budgetary difficulties and technical reasons, though there are certainly some grounds for thinking that the reasons lie elsewhere.

Sources at the Department of Space and ISRO have flatly denied a report in a British Interplanetary Society journal that India had agreed to make port facilities available to Soviet recovery ships in the Indian Ocean in return for Soviet launching of India's first satellite (weighing about 300 kilograms).

It is acknowledged a request for port facilities, for space tracking and recovery ships, was in fact received from the Soviet Union sometime in 1973. But the sources maintain that no decision has yet been taken in this regard and that this has nothing to do with the Soviet Union's agreement to launch the satellite, the two being entirely separate matters. It is believed that Indian scientists have been invited to install research instruments in future Soviet space vehicles to the Moon and other planets, but the matter has yet to be discussed and finalised. A joint meeting of the space officials of the two countries is to take place in February this year for discussions on collaboration in space research.

Meanwhile, the Prime Minister recently told a consultative committee meeting that the original cost estimate of Rs15.6 crores sanctioned in 1973 for the satellite launch vehicle project would probably need to be escalated. "Apart from the increased cost, the special circumstances prevailing during the past two to three years have created difficulties in the way of speeding up the progress of the project", it was said. "Barring unforeseen problems, it is possible to achieve a satellite launch in 1978", the committee was informed.

The launch vehicle project is aimed at developing a four-stage rocket to fire a 40-kilogram satellite into orbit 400 kilometres up.

Full allocations of funds for the projects of the Department of Space have not been forthcoming, and this has resulted in an adjustment of priorities. □

Nuclear fuel plant mystery

by Colin Norman, Washington

A TECHNICIAN employed at a nuclear fuel fabrication plant in Oklahoma died in an automobile accident on November 13 last year when her car careered off a highway and struck a concrete culvert. The crash has brought national publicity to a bitter dispute over safety standards at the plant and sparked off a string of bizarre allegations which could reverberate for years.

When the accident occurred, the technician, Karen Silkwood, was on her way to meet an official of the Oil, Chemical and Atomic Workers' Union (OCAW) and a reporter from the *New York Times*, to discuss charges of lax safety precautions at the plant and allegations of faulty manufacture of plutonium fuel rods. Police investigators ruled out foul play and said she probably fell asleep at the wheel, but the union hired an automobile crash expert who concluded that she may have been forced off the road by another car. The matter is now under investigation by the FBI.

Although that event was mysterious enough, a series of reports by the Atomic Energy Commission (AEC) which investigated Miss Silkwood's charges have added yet another element of mystery to the affair.

Miss Silkwood and officials of OCAW launched the AEC investigations when they met AEC officials on September 27 last year to give details of 39 separate violations of safety regulations

which they alleged had taken place at the fuel fabrication plant. Operated by the Kerr-McGee Nuclear Corporation at Crescent, Oklahoma, the plant manufactures plutonium fuel rods for the Fast Flux Test Facility, an experimental breeder reactor installation being constructed in Washington State.

In the meantime, Miss Silkwood discovered on November 5 that her hands were contaminated with plutonium after she had been working with a glove box handling plutonium samples. She was decontaminated and found to be free from plutonium when she left the plant later that night. But when she reported for work the next morning, her hands, forearm, neck and face were again found to be contaminated with plutonium.

Then, on the morning of November 7, a nasal smear taken when she reported for work indicated a high level of plutonium contamination yet again, and urine samples she had collected over the previous two days were also found to contain significant levels of the substance. A subsequent check of her apartment led to the discovery of microscopic amounts of plutonium in the bathroom, kitchen and refrigerator, and her flatmate was also found to have two spots of low level contamination on her skin.

An investigation of those incidents was launched by the AEC immediately, but a report released by the commission last week simply adds to the confusion. The AEC investigators found, in short, that Miss Silkwood's contamination "probably did not result from an accident or incident within the plant",

and that the plutonium discovered in the urine samples "was not present in the urine when it was excreted". Finally, they suggested that Miss Silkwood "did ingest some plutonium on or about November 7, 1974".

The essence of those findings is that the AEC believes that Miss Silkwood may have contaminated her own skin, swallowed a tiny amount of plutonium and added plutonium to her urine samples. No explanation is offered of the reasons for taking such action, although others have speculated that she may simply have wanted to draw attention to the allegations of lax safety precautions at the plant. If so, self-contamination with plutonium seems an incredibly drastic step to take.

The Oil, Chemical and Atomic Workers' Union has sent the AEC's report to some scientists for review, on the basis of which Mr Anthony Mazzocchi, the union's Washington representative, said in a report to Kerr-McGee's union members last week that because Silkwood had a high respect for plutonium, "it is inconceivable to us that she would contaminate herself or her apartment deliberately". He suggested that "there is enough evidence to cause an investigation to be commenced into the possibility that Silkwood was intentionally contaminated by sources unknown to her", and called for the AEC to reopen its investigation.

Meanwhile, the AEC investigated the other 39 allegations of safety violations raised by Miss Silkwood at the September meeting, and came up with some evidence of inadequate precautions. The report, however, largely exonerated the plant management and the AEC termed most of the incidents minor.

A close reading of the report, however, indicates that even though some of the allegations may have been exaggerated, the AEC's findings still paint a fairly dismal picture. Take, for example, the allegation that there is a turnover of 60% of the work force at the plant each year. The claim, says the AEC is not substantiated because the actual turnover is 35%, which is still an amazingly high figure. Similarly, the AEC says that the allegation that 80% of the work force has less than two years of experience is incorrect. The actual figure is 62%.

● In Britain, the possible dangers of working with plutonium have been highlighted in the past few weeks by reports that the health records of workers at the British Nuclear Fuels Windscale works showed a small but significantly higher incidence of leukaemia than might be expected. Although the statistical validity of these results is still being debated, at least one union is undertaking an investigation into the situation. □

How do you get over the problem of calcium loss, particularly from the knee joints, during long space voyages? Recruit double amputees for astronauts, says Dr John M. Vogel, a specialist in nuclear medicine, working at the University of California at Davis.

As nobody has yet found a successful means of preventing calcium loss at the knee joints during periods of prolonged weightlessness, the Californian team is seriously investigating the next best thing: dispensing with knees altogether. As there are people around who have already lost their legs, why not make use of them as space pilots?

There could be many benefits from having legless astronauts. It might be possible, for example, to carry more of them in a given size of spacecraft than of the conventional biped astronauts employed so far. Double amputees would also presumably eat less food, and breathe less air; and, being more compact, would probably find the cramped living conditions of

a spacecraft more comfortable than would two-legged astronauts. And the use of artificial legs instead of real ones during space walks or sorties on to planetary surfaces may prove a positive advantage. Not requiring the protection of a space suit, such legs would be in their natural environment in space rather than being less useful than real legs, as they seem on Earth. And as extravehicular activity would be carried out largely with the help of machinery anyway, with planetary 'buggies' and the like, the fewer human limbs to cater for, the better.

Of course, this whole philosophy could get out of hand. One could imagine armless astronauts ultimately, or perhaps, as medical science advances, even more bizarre developments. The Californian team is making its study in preparation for a possible voyage to Mars, which would take about six months with present technology. So, double amputees watch out for the advertisements.

from Peter Goodwin

Two Israeli university presidents, Professor Yuval Ne'eman of Tel Aviv University and Professor Moshe Prywes of Ben-Gurion University of the Negev, have submitted their resignations in recent weeks. Each has his own reason: Ne'eman has accepted a top post in the Defence Ministry and Prywes has been put in charge of all Negev medical services (in addition to directing the operations of Ben-Gurion University's newly established medical school). But their decisions may also have been influenced by the increasing difficulties faced by all local university presidents, who are striving to meet costs that have risen by 30% to 40% in one year while income—from Israel's University Grants Committee and other sources—has remained virtually static or has even declined.

Their problems are further complicated by charges in the press that too much money is being devoted to higher education at a time when insufficient funds are available for primary and secondary schools. Much of the criticism is extraordinarily simplistic: comparisons are made, for example, between the sum spent on the education of a primary school child and the money spent on the training of a university student, without taking into account, among other things, the university's role as a research centre.

Also stemming from the current economic situation is the government request that Israeli professors either give up their sabbatical leave this year, or, alternatively, spend it at another local institution. Professor Amnon Rubinstein, of Tel Aviv University, believes the request is justified "in a year of military tension and economic crisis." His colleague at Tel Aviv University, Dr Benjamin Rulf, has, in contrast, received the idea very coolly. Rulf warns that overseas sabbaticals are an essential safeguard against "scientific degeneration."

It now seems that the professors who are supposed to go on sabbatical leave this year will be asked to remain in Israel, but that no binding regulations will be brought in.

Economies, meanwhile, are proceeding in other spheres. Classes at the Hebrew University, to give just one example, are ending this winter at 20.00 instead of 21.00 in order to cut down on lighting and heating costs. The university has also announced a freeze on the hiring of new personnel to fill vacant posts.

But such paring down around the edges will not be sufficient. Barring some drastic and unlikely increase in funds from either Israeli or overseas sources, large scale dismissals are inevitable. In fact, Tel Aviv University

has already stated that 400 posts will have to go—some through natural wastage, others through dismissals. Other universities are likely to follow suit.

● Research grants from overseas bodies continue to play an important role in keeping afloat Israeli institutions of higher learning. This is particularly true at the Weizmann Institute, whose scientists manage to obtain a good many grants in the face of fierce competition.

Among the recent grants to be announced at the Weizmann is one of \$146,000 from the National Cancer Institute of the US National Institutes of Health to Professor Leo Sachs for research into the carcinogenic properties of chemical compounds. It will help

some 1,500 or 1,600 newly granted patents (about the number issued in Israel, to both local and overseas applicants, in the course of a full year).

● An (unpatented) Israeli development which should be of interest overseas is "Help Pollution", a game of the Monopoly ilk now being used as a teaching aid in high school biology classes. Created at Bar-Ilan University by Dr Uri Yoel, it is won by the player who is most successful in his attempt to prevent pollution of the Sea of Galilee, the country's main fresh water reservoir, which is facing a very real pollution threat from the inflow of municipal sewage and agricultural fertilisers, as well as from the rubbish left around its shores.

As in Monopoly, players acquire property around the lake and then try to increase its value. To do so they must prevent pollution of their land and of the lake by, among other things, investing money in anti-pollution measures. Uncertainty is added by accidents, such as DDT seeping into the water.

Letter from Israel

from Nechemia Meyers

Sachs further develop his method, already adopted overseas, for testing suspect chemicals in tissue culture rather than in experimental animals.

German funds are as important a source of support of Weizmann Institute research as money from the USA, the traditional sugar-daddy of international science. The Minerva Fund, a subsidiary of the Max Planck Society, is alone providing DM5 million to finance 64 projects at the Weizmann Institute during 1975.

Industrially sponsored research at the Weizmann (and elsewhere) is growing, but still leaves much to be desired. Rehovot scientists, for example, have \$1.25 million in industrial research contracts, 70% from overseas companies and 30% from Israeli ones. Most agreements, negotiated by the Yeda Research and Development Company, involve plastics, chemicals or pharmaceuticals.

● Mr Issac Fleischmann, Director of the US Patent Office's Information Service, suggested during his recent visit that Israelis, in addition to developing their own processes and devices, should make a more vigorous effort to exploit those developed in other countries.

Fleischmann pointed out that relatively few patents have been issued in Israel, which means that hundreds of thousands of ideas protected elsewhere may be borrowed freely for use here. He found it strange that there are so few Israeli subscribers to the US Patent Office's *Official Gazette of Patents*, which each week carries a summary of

● While Israeli schools teach youngsters to protect their country's environment, Israel's national radio and television stations are playing a song which glorifies a man for inscribing his name on a public building. He is Baruch Jamili, a soldier in the 1948 War of Independence, who chose to write his name in tar on a water pumping station near Jerusalem. Seeing the name 25 years later, the song writer and singer Shlomo Artzi wrote "The Ballad of Baruch Jamili", which presented Jamili as a war hero and won the last Israel Song Festival.

The outraged Nature Reserves Association promptly issued a statement strongly attacking the song, which, it fears, will encourage non-heroes to inscribe their own names on public buildings.

Graffiti are not a new problem here, as witnessed by the inscriptions that have been left all over the area for untold centuries. But the signature of a Crusader knight on the wall of a dining hall in Sinai's Santa Katerina Monastery is history whereas a signature added by a contemporary visitor is regarded as vandalism.

A unique attempt to let the graffiti artists express themselves, and yet safeguard the environment, is being made at a scenic canyon in the Negev desert, near the Red Sea port of Eilat. Taking a positive approach, the local authorities have set aside a special slab of rock where visitors are invited to carve or write their names.

They are politely requested to leave the rest of the canyon untouched.

Corking the Chunnel

from Angela Croome

THERE have been complaints that the cancellation of the British-French Channel Tunnel Project last week by Anthony Crosland, Secretary of State for the Environment, was both hasty and premature. But this seems a point of view that is difficult to justify for a scheme that has been in the pipeline (as it were) for well over a hundred years. Indeed, a look at the 'on/off' history of this latest Chunnel plan (going back to the 1962 White Paper *Proposals for a Fixed Channel Link*) it is remarkable that the scheme survived the rejection in 1968 by both the British and French governments of the industrial proposals they had called for the year before. Rather than projecting an image of the 'white heat of technology', which was the watchword of the then Wilson government, the plan always had a gaslit and fustian air about it.

Tunnelling was above all a nineteenth century enthusiasm. It was indeed a technological innovation then—an extension of the techniques used in mining deeper and in some cases (as in Cornwall) under the sea. The Cornish engineer, Richard Trevithick, was called in to complete the first Thames tunnel (between Rotherhithe and Limehouse) in the early 1880s. With the aid of picked gangs of stout Cornish miners accustomed to working in a crouched position and in unbelievably horrible conditions he would certainly have succeeded had the money not finally run out only 200 feet from the far end. There is no trace of Trevithick's tunnel today. It took the Brunels, father and son, another 40 years to bring off the first Rotherhithe tunnel for wheeled traffic (now used by the London Underground). There were several cave-ins and a number of miners also died from the "tunnel disease"—a lung complaint attributed to the poisonous air in the workings. Many technological advances were made in completing "The Thames Tunnel" as the Brunel venture came to be called, including the special shield designed by Isambard Kingdom Brunel on the system of the burrowing shipworm *Teredo navalis* to hold the newly bored walls in place until lining was completed. But bridges increasingly superseded tunnels as a traffic link as the century progressed. And it is hard to see that there is any comparison at all in convenience, flexibility and 'passenger satisfaction'. The prospect of travelling not merely underground but underwater for the best part of an hour is a nightmarish prospect for many people.

Despite the long gestation period of

To Paris by carriage (with a gaslit and fustian air).

the Chunnel scheme, and the various assessments and reappraisals, the Cairncross review, the revised rail-link proposals and so forth, there has never been the sense of a real solution to the cross-channel traffic problem but rather a look of amateurish gimmickry. Has a serious study ever been made of a cross-channel bridge? Would it really be more vulnerable than a tunnel? Some years ago Desmond King-Hele put forward the virtues of a channel dam—and not entirely as a *jeu d'esprit*.

France is better linked to Britain than is any other European country. Nor can there be any question that another link with the capacity of the present channel ferries concentrated into the south-east tip of Britain would increase the congestion of the most crowded part of the country. There is considerable resentment already—in Belgium for instance—that so much freight has to be routed through France, picking up an additional and particularly swingeing tariff on the way. This has also put up the price of the goods in Britain.

There seems an excellent case for new links to the continent from the east coast of Britain and the more westerly of the south coast ports, thus better distributing traffic and avoiding the London bottleneck, and also bringing welcome growth to the less industrialised regions. This need not be motorised traffic either—whole trains travel by ferry in Scandinavia. The south coast port authorities have already indicated that they could handle twice the present traffic, which corresponds closely with the amount predicted for the tunnel at its planned opening date in 1981.

The potential of the hovercraft link seems to have been ignored in the predictions and calculations. Yet this type of ferry (using the current SRN-4, a 350-ton vehicle) takes only 30 minutes to cross the same route as the pro-

jected Chunnel, the journey in which was expected to last nearer an hour. Five craft now carry 25% of all passenger traffic on this route. Docking requirements, and therefore land use, is minimal. Apart from their rapidity, they perhaps represent the most flexible type of sea link yet devised. It is paradoxical that while the French have felt obliged to cry "perfidious Albion" again over Crosland's tunnel decision the partly state-subsidised Bertin company is hurrying to complete a larger cross-channel hover-ferry, the Naviplane 500, which is expected to be at the trials stage in 1976 and no doubt in competition with the British service shortly after. That there are no plans to develop a larger version of the SRN-4, nor a successor, is a matter of major concern in the industry.

Which brings one back to the lack of a true overall plan for traffic and transport development in Britain. What happened to the comprehensive independent study commissioned by the Ministry of Technology in the mid-1960s?

There is no reason to doubt that modern technology could build a channel tunnel if the nation was prepared to spend enough on it. If a prestige gesture for a technologically advanced (and united) Europe is a worthy object, then a Wilson-D'Estaing bridge would be much more telling than a Macmillan-De Gaulle tube. If better communications and a good return for money is the point, then the Secretary of State for the Environment has done the right thing and not a moment too soon, though it will be important to follow up a sensible saving with a sensitive alternative solution or solutions. The one bit of advanced technology that one must regret will not now come to fruition is the project of certain citizens of Kent for a Great Channel Tunnel Cork—to plug the great channel tunnel's mouth when it was finished. □

correspondence

Neuberger on nutrition

SIR,—I have considered myself a nutritionist for nearly 40 years, and I doubt whether even in the 1930s I would have ignored the teachings of John Boyd Orr and Frederick Gowland Hopkins in order to accept the description of nutrition that forms the first sentence of the Neuberger report: "The science of human nutrition is mainly concerned with defining the optimum amounts of the constituents of food necessary to achieve or maintain health."

Nutrition, on the contrary, is to do with the whole relationship between man and what he eats, that is, it is to do with food: how food is produced; what determines which foods we eat and how much; what the constituents of food are; which of these the body requires and in what amounts; how these constituents are dealt with in the body and what functions they perform; what happens when the required amounts of the required constituents are not provided or are exceeded; what steps can be taken to avoid these differences between what is needed and what is consumed. Nutrition, therefore, has reference to economics, anthropology, sociology, demography and psychology, as well as to chemistry, biology, biochemistry and physiology. In particular, nutrition is the one science that can least afford to remain in the laboratory; it concerns every single human being, every single day of his life.

What enthusiasm the report shows is confined largely to its summary of existing knowledge of the biochemical aspects of nutrition, and much of its recommendations for further research are also in this area. There is only an occasional brief reference to nutrition as it affects the whole body and an even less frequent nod towards the need to know more about people's nutritional behaviour. This bias is really not good enough; the human body exists together with other human bodies in a social and cultural environment, and important as biochemistry is, it is as important—and possibly more so—to know what determines the diets of different people, in different groups, at different times. Certainly we need to know more about energy transformation in the body and the mechanisms that control body weight and body composition. But of more immediate relevance to problems of malnutrition is the search for answers to quite dif-

ferent questions: Why do some people find it easy to cure their obesity and others find it difficult? Why are so many of the obese so easily persuaded that they can solve their problem by eating Ryvita or yoghurt, or by swallowing slimming pills that contain nothing but aperients, or by going to expensive but quite ineffective slimming clinics?

In this country, and in other countries in the western world, there is a considerable and increasing demand for so-called health foods. What is it that makes so many people entirely ignore the knowledge so laboriously acquired by nutritional research in favour of the incorrect or misleading information that makes them buy brown sugar, brown bread, sea salt, honey and vitamin pills to ensure that they are adequately nourished, or that makes them believe that there is special virtue in brown eggs or in vegetables grown with compost rather than with chemical fertilisers? And why do we continue to act as if it is still true that adequate nutrition in the industrialised countries is largely a matter of economic circumstance—as if all that matters is that a family shall have an adequate income—when it has been demonstrated in the USA, for example, that there has been an increase in the proportion of families eating a poor diet at the same time as family incomes have increased? Again it is just not good enough for the nutritionist to ignore these views, held as they often are by sincere and highly intelligent people, however misguided. Even less is it good enough for us to smile a superior smile and tell such people—and tell each other with a wink—how stupid these views are.

It is because nutritionists know that such matters are important that research carried out in departments of nutrition today is concerned not only with the physiological and biochemical problems that the report concentrates on so heavily, but with broader subjects too: the factors that determine food choice, the influence of diet on behaviour and of behaviour on diet, the assessment of attitudes towards foods and nutrition, and the differences between what people think about food and what in fact they eat. In the university department that I know—that at Queen Elizabeth College, London—more than 300 research papers were published between the start of the degree course in nutrition in 1953 and my retirement from the Chair of

Nutrition in 1971.

The report deplores the "relative neglect of human nutrition" as a subject for research. I suggest that this neglect is, more than anything else, a consequence of the existence of a myth about what nutrition is. The myth is that nutritional science is mostly to do with "defining the optimum amounts of the constituents of food". It is the narrowness of this account of nutrition that has been largely responsible for the subject's failure to attract either the research support or the attention of young scientists to the extent that its interest and importance deserve. Although the report deplores these consequences, it perpetuates the myth that has helped to create them.

Yours faithfully,

JOHN YUDKIN

London NW3, UK

Asbestosis

SIR,—The best comment to be made on P. F. Holt's letter (January 10) about complacency over asbestosis is contained in the latest Annual Report of HM Chief Inspector of Factories, which says in relation to new cases of asbestosis and mesothelioma, and the latest figures, that they "reflect conditions in the past when, in the then state of knowledge, it could not be ascertained with any certainty what levels of air contamination by asbestos dust would endanger health". Later, describing a major long term medical environmental survey of asbestos workers, he says: "In Phase II of the survey, which embraced the larger manufacturers of asbestos products, 5,000 workers were medically examined and 700 representative personal samples were taken in the workers' breathing zones over 4-hour working periods. The results, which were most encouraging, showed that 92.6% of the dust counts taken were below the very stringent hygiene standard of two fibres/ml and reflect the very great efforts made by the major firms in the industry to improve standards of control."

Mr Holt's references to a London life of insulation from reality are wide of the mark. I work in Manchester, the geographical centre of the British asbestos industry, and spend much of my time in asbestos factories.

Yours faithfully,

W. P. HOWARD

The Asbestos Information Committee,
Manchester, UK

Manpower needs

SIR,—We read with interest your editorial (January 3) entitled "Manpower needs are not so easily estimated". We feel that, although you made some telling points, the bluntness of your critical edge and the scathing tone caused some important aspects of manpower problems and the role of the Manpower Services Commission (MSC) to be lost. The baby, to our dismay, went out with the bathwater.

First of all, the nature of the MSC and its relationship to the Department of Employment are by now well known to those with a practical interest in the field and are easily obtained. Perhaps the opportunity to publicise its role might have been taken by a note on the fly leaf of the report on the manpower implications of offshore oil and gas. It is a pity, then, that you got your facts wrong and referred to both the MSC and the Petroleum Industry Training Board as agencies of the Department of Employment. And in drawing attention to a misprint you tempted providence in the form of the printer's devil, who inserted another in the same line of your own piece.

So, please let all of us eliminate, as you say, the "emotive turn of phrase" and give some careful thought to the critical problems of manpower—of which the manpower to enable us to exploit offshore oil and gas is not the least.

Perhaps the wisest statement of your editorial was the title: manpower needs are not so easily estimated. The UK has devoted ludicrously small resources to studying and forming policy about manpower. It is, after all, perhaps our most critical national resource (and that statement is fast becoming a cliché) and yet, as you rightly point out, we have not had the major, in depth, study that is really necessary to provide a sound basis for action at all levels in respect of skills and manpower needed to exploit the North Sea.

In such a situation, the arrival of the MSC as an independent voice is an important step forward. Its role and composition was established by the Employment and Training Act 1973. The MSC is financed through the Secretary of State for Employment (but is not part of the Department) and through the Training Services Agency co-ordinates the operation of the Industrial Training Boards.

At this early stage, it is surely appropriate for the MSC to promote and publicise pieces of work, particularly those that summarise what is known. In the process, some ideas will come forward to be dismissed and some good work will be overlooked. All this will draw attention to the paucity of current knowledge.

The report that you criticise, to quote the introduction, attempts to provide an overview by drawing together the threads of previous studies. There is no guarantee that a literature search will provide the answers to any problem. In the circumstances, and in view of the public debate that is taking place, the MSC is surely right to publicise the findings, but not to endorse necessarily the conclusions reached. In that way we will all learn.

Perhaps we could also take the opportunity to make some comment on the problems of the supply of qualified manpower, drawing on some of our own research. By and large, the employing organisations which create demand for people, on the one hand, and the education and training institutions which create a supply, on the other, operate pretty well independently of each other. Any impression that we can forecast the demand for (for example) geologists and then set up the courses to provide them is so oversimplified as to be useless. Accurate forecasts are not possible in any case. We have to know more about the absorption of graduates into the economy—some emigrate, others go back into education, others move rapidly away from straight application of their basic discipline. More needs to be learned about how university courses might develop in the interests of the individual and society (taking a very long term view). Even if we knew precisely what we wanted, there remains the question of how the educational system and the people in it react or might be helped to react. Industry is notoriously weak at articulating a considered view (though you are right to say that many companies prefer to undertake specialist training of geologists themselves).

Thus, in regard to many aspects of manpower, we have an extraordinarily complex system working within a changing and unpredictable environment in which the components have very strong needs of their own.

Manpower needs are indeed not so easy to estimate. We trust we may see more encouragement of and support for those who are only now beginning to grapple with the problem.

Yours faithfully,

JOHN LAWRENCE
GRAHAM ATKINSON

International meetings

SIR,—The letter from S. Peller (December 13) is similar to so many of the past few years and raises again the recurring, vexing problem of the location of international conferences. Clearly

assurances by some governments of entry to all participants are meant by these governments to be honoured in the breach. Starting from the premises that international scientific meetings should, in fact, be open to all qualified scientists, and that the internal affairs of the host country should not be interfered with, I should like to make the following suggestion.

Each international union should set up a committee to investigate complaints from *bona fide* scientists who have been barred from a meeting. If the charges are verified, then the union would bar that country as host for other meetings for a period of five years, the restriction to apply even to meetings already scheduled. Thus any country would have the choice of playing politics or hosting international meetings, but not both. Of course, some measures would also have to be taken to prevent the scientific union itself from becoming political, as has happened to UNESCO.

Variants of this method could also be considered. Thus a country which does not allow its scientists free access to meetings, such as, for example, the Soviet Union, could be barred from having any of its scientists attend such meetings.

Yours faithfully,

SAM SILVERMAN
Lexington, Massachusetts 02173

Alien message

SIR,—If an alien civilisation should chance to receive the radio message broadcast to the stars from the Arecibo telescope (January 24) it would be fully justified in reversing the charge for any reply. I make this assertion because, to judge from your illustration, the original communication was itself reversed, vertically. Which is to say, sir, it was upside down (not that the concept of tops and bottoms means very much in terms of inter-galactic messages).

As the message stands, an alien listener might just about make out that we are trying to tell him something about a man who appears to be balancing on his head at the top of a Maypole.

I for one shall be surprised if anybody (from this galaxy or the next) troubles to reply to such blather, unless it is to tell us that his chaps go in for Morris dancing while walking on their hands.

Yours faithfully,

B. JOVE

Hove, UK

ED—Sorry; the message was garbled during transmission from the *Nature* office to the printing works. So much for the march of progress.

news and views

New nitrogen-fixing symbioses *in vitro*

from John Postgate

THE truism that rhizobia, the symbiotic nitrogen-fixing bacteria, never fix nitrogen away from a leguminous host plant may seem, to an outsider, more of a dogma than an experimentally based fact. But a convention of scientific publication is that one rarely publishes purely negative findings, so the absence of documentation in the scientific literature of this failure does not do justice to the effort which has been put into the question: the truth is that many workers throughout the world have attempted, without success, to obtain fixation by pure cultures of rhizobium *in vitro* using all sorts of plausible conditions, such as nitrogen starvation at low oxygen tensions, presence of plant extracts, glutamine mutants and so on. A report in 1971 (*Nature*, **232**, 173) in which research workers from the laboratories of Dupont de Nemours obtained nitrogen fixation in a tissue culture of callus from a soyabean root, infected with *Rhizobium japonicum*, was greeted with excitement as a step in the direction of simplifying this nitrogen-fixing association. Fixation, though slight, was apparently taking place without the nodulation, leghaemoglobin and bacteroid formation seemingly necessary in the intact plant.

Though confirmatory reports gradually appeared from other laboratories, some scientists remained sceptical. Ethylene formation from acetylene, a diagnostic reaction for the nitrogen fixation enzymes, was the criterion used in these experiments; but ethylene is a normal product of plant metabolism. Were the controls for endogenous ethy-

lene as reliable as they looked? In addition, persons working with such material know well that it is very difficult to rid callus cultures of bacteria completely and the contaminants which persist are often capable of nitrogen fixation alone. They also knew that it is difficult (because of the gummy nature of the colonies) to be wholly certain that cultures of rhizobium are pure. Finally, the critics knew that aerobic organisms—bacteria or plant cells—could scavenge oxygen from a micro-environment and enable anaerobes such as *Clostridium pasteurianum* to grow and fix nitrogen. Were the microbiological controls of the early experiments adequate? Certainly they were cursory as described in the earliest publications and sometimes even absent.

Considerations of this kind account for the admirable preoccupation with cultural purity noticeable in two important developments, reported simultaneously from Canada and Australia in this issue (pages 350 and 351). Both papers present evidence that rhizobia, at least of the slow-growing 'cowpea' type, can form associations *in vitro*, not only with callus from the leguminous plants with which they associate in nature, but also with callus from plants which do not normally nodulate and even with callus from quite unrelated plant groups.

Like the Dupont group, all the workers obtained their rhizobia from Dr Burton of Milwaukee. Child not only checked for contaminants carefully but used three different strains of rhizobium and callus from six different types of plant, thus diminishing the

possibility that he is handling artifacts of contamination; Scowcroft and Gibson have also checked their material microbiologically and, in addition, with isotopic $^{15}\text{N}_2$, thus completely disposing of any possibility of errors due to endogenous ethylene production by the plant material. So, accepting that their meticulous negative tests for contaminating nitrogen-fixing microbes were adequate, the reality of effective nitrogen-fixing associations between slow-growing rhizobia and plants as remote from legumes as tobacco or the monocotyledonous wheat seems established, at least *in vitro*. It is entirely consistent with these findings, as both papers acknowledge, that Trinic recently discovered a natural nitrogen-fixing association between a slow-growing rhizobium and a non-leguminous plant of the genus *Trema* (*Nature*, **244**, 459; 1971). But the new experiments go further than this: their design is such that the plant callus is grown on a membrane, and this lies on an agar surface which has been infected with rhizobia. By removing the membrane the plant material can be removed from at least a proportion of its associated rhizobia. Yet the rhizobia remaining after the plant material had been removed continued to fix nitrogen for several hours. For the first time, therefore, rhizobia have been induced to fix nitrogen away from the plant, though the ability does not persist on subculture.

Physiological studies made it clear several years ago that rhizobia are the sites of nitrogen fixation in the nodule. Whether or not they possess the genetic information necessary to form the enzyme system is still not certain, but it is clear that, to use their information, they need something from the plant. The new experiments suggest that the material needed is diffusible and that its effect lasts for several hours. In the short term, biochemists, plant physiologists and geneticists will await eagerly the characterisation of the diffusible factor and the understanding of its apparent role in the regulation of the nitrogen fixation genes of rhizobium. In the longer term, these studies are a useful step towards the establishment of nitrogen-fixing associations between rhizobia and all sorts of agriculturally important crops and forage plants.

Elm bark disease in Australia

from Allan Rosel and John French

THE smaller European elm bark beetle (*Scolytus multistriatus*) was discovered in 1974 to be attacking elms in and up to 123 miles from Melbourne. This beetle is one of the main carriers of the Dutch elm disease fungus (*Ceratocystis ulmi*). It has not previously been recorded in Australia although the number of emergence holes in the bark of infested elms suggests that the beetle has been established in Victoria for several years. The beetle has been

sought but as yet not found elsewhere in Australia. A survey is continuing.

Microbial examination of beetles and attacked trees has failed to reveal the presence of the Dutch elm disease fungus. Dr S. L. Wood of Brigham Young University, Utah believes that the disease, if present, would have been apparent by now. It seems that in Australia, as on the west coast of North America, the carrier is present but not the disease.

New steps in the formation of phage T4 heads and DNA packaging

from P. J. G. Butler

THE large bacteriophage T4 has a long history of interest and current developments are maintaining this standard. Since it was shown to have a DNA-containing head connected by a hollow tail to the fibres which are involved in the attachment to the host cell, interest has centred on the mechanism for the assembly of such a complex structure. As shown by the groups at Caltech and Geneva, it is particularly suitable for such study because of the ability of the incomplete fragments, which accumulate in cells infected with mutants in many of the assembly steps, to form complete phage either by *in vitro* complementation with the fragments from another suitable mutant (Edgar and Wood, *Proc. natn. Acad. Sci. U.S.A.*, **55**, 498; 1966) or by subsequent activation of the blocked step (for example by the removal of a temperature sensitive infection from a non-permissive temperature to a permissive one).

The assembly occurs as a series of subassembly steps, with the head, tail and tail fibres being assembled separately and then joined together, first the tail on to the DNA-containing head and finally the tail fibres added to the fibreless particle to give the complete phage (reviewed by Wood *et al.*, *Fedn. Proc.*, **27**, 1160; 1968). During the infection of a host cell, the incoming DNA is expelled from the head through the tubular tail without any requirement for an energy source. This has led to speculation that the DNA is packed into the head in a special way, as if under pressure, so that its release occurs like that of a spring. A highly condensed state for the DNA is also required for the total amount to be packed into the volume available.

Head assembly

Unlike a number of simpler viruses, the heads of T4 seem to be largely assembled before much of the DNA is inserted into the pre-existing shell (Luftig *et al.*, *J. molec. Biol.*, **57**, 555; 1971; Simon, *Proc. natn. Acad. Sci. U.S.A.*, **69**, 907; 1972), and recently some of the steps have been described. A hierarchy of partially characterised steps (Laemmli *et al.*, *J. molec. Biol.*, **49**, 99; 1970) leads to the formation of the first recognisable head structure, prohead I, with a sedimentation coefficient of about 400S, containing at least four protein species (P23, P20, P22 and IP III) but no DNA (Laemmli and Favre, *J. molec. Biol.*, **80**, 575; 1973). These particles are converted to prohead II (about 350S) by the cleavage of

the major protein (P23) to give P23*. This cleavage seems to require the action of two distinct phage proteins, P21 and P24, and failure of either of these leads to the accumulation of 'τ-particles' (Epstein *et al.*, *Cold Spring Harb. Symp. quant. Biol.*, **28**, 375; 1963; Laemmli *et al.*, *J. molec. Biol.*, **49**, 99; 1970) which are smaller than the normal heads.

Though the τ-particles produced in the absence of functional P21 seem to be completely aberrant and cannot be rescued to form normal heads (Laemmli and Johnson, *J. molec. Biol.*, **80**, 601; 1974), those formed without P24 can act as a subassembly for head formation, without being disrupted in the process (Bijlenga *et al.*, *Nature*, **249**, 825; 1974). Analysis of the proteins in these 24 τ-particles shows that they

contain uncleaved P23 and that this is converted to P23* upon activation of P24, and it thus seems probable that these τ-particles represent an intermediate in the pathway between proheads I and II (Bijlenga *et al.*, *J. supra-molec. Struct.*, **2**, 45; 1974).

The conversion of prohead II into prohead III (550S) again involves the action of two phage proteins, P16 and P17, and is the first step in which the proheads become associated with the replicative DNA and the DNA packaging starts. During this conversion of II to III the cleavage of two further proteins, P22 and IP III, begins. This process is finished during the final maturation of the prohead III into mature phage heads. This requires the action of yet another protein, P49, and goes in close parallel with the com-

The magnetic field of Jupiter

from D. Stannard

THE latest development in the exploration of the Solar System by spacecraft came with the arrival of the Pioneer 11 probe at Jupiter in early December. Following almost a year after Pioneer 10, its predecessor to the planet, Pioneer 11 swept within 0.6 planetary radii (R_J) of the Jovian surface before continuing on its way towards the planned encounter with Saturn in 1979. With remarkable promptness, Acuna and Ness present a preliminary interpretation of the Pioneer 11 measurements of the structure of the inner Jovian magnetic field in this issue of *Nature* (page 327).

Ground-based studies of the radio emission from Jupiter over the past twenty years have suggested a picture of the field structure which is basically that of a magnetic dipole, with the axis of the dipole inclined by just under 10° to the rotation axis of the planet. Asymmetries which are present in both the decametric (noise burst) and decimetric (synchrotron) radio emission suggest that there may well be fine structure associated with the dipole field at distances of between 1 and 2 R_J from the planet. In particular there is evidence of a localised field distortion close to the longitude of the magnetic pole in the Northern Hemisphere (Conway and Stannard, *Nature*, **239**, 142; 1972).

The magnetometer measurements from Pioneer 10 confirmed the essential dipole character of the main Jovian field at distances greater than the spacecraft's closest approach of 2.8 R_J . A better fit to the data in the inner field region was however obtained using a 'dual dipole' model, with a weak secondary dipole close to the position of the field anomaly indicated by the radio astronomy measurements (Smith *et al.*, *J. geophys. Res.*, **74**, 3501; 1974).

The close approach of Pioneer 11 to the Jovian surface has now enabled the structure of the inner field region to be studied in detail. As shown in Figure 3 of Acuna and Ness's paper, the field is indeed complex, and at least an octupole expansion is required to describe the data. Particularly prominent is the asymmetry in the pole strengths of the two hemispheres, with a field of 28 Gauss at the north magnetic pole, and only 16 Gauss at the south. The magnetic equator within 2 R_J is highly distorted and steeply inclined with respect to the zenographic equator. With this detailed information about the field structure it should now become possible to perform more reliable quantitative calculations on the radio astronomical data to enhance our knowledge of the physical processes in the Jovian magnetosphere.

pletion of the DNA packaging. While a large part of the cleaved IP III remains in the mature heads, as IP III*, most of the cleaved P22 is lost and only the 'internal peptides' remain in the mature heads (Showe and Black, *Nature new Biol.*, **242**, 70; 1973).

Laemmli and Favre had shown that prohead II contained less than 1% of the DNA content of full heads and obtained some evidence that the prohead III contained about 50% of the DNA. This estimate has now been confirmed by the incorporation of bromodeoxyuridine into the maturing prohead III particles when a temperature-sensitive P49 is activated by a temperature shift, with further protein synthesis inhibited (Laemmli *et al.*, *J. molec. Biol.*, **88**, 749; 1974). After isolation of the DNA from the mature phage it was cleaved at the sites of bromodeoxyuridine incorporation, by exposure to ultraviolet light, and then found to have been reduced to about half its intact molecular weight. Using a similar technique, these authors also confirmed that the 24 τ -particles (and, by presumption, prohead I) contained little DNA.

The problem of the length determination for the DNA packaged into a mature phage particle has been further investigated using the giant heads produced by exposure of infected cells to L-canavanine and then deinhibition of the DNA synthesis with arginine. After isolation of narrow length classes, of about 4x and 8x normal head lengths from T4 and 12x to 13x from T2, and very gentle lysis of the phage to give intact DNA, it has proved possible to measure the molecular weight of the largest DNA molecules in the giant heads (Uhlenhopp *et al.*, *J. molec. Biol.*, **89**, 689; 1974). Using the technique of viscoelastic relaxation, these authors determined not only the molecular weight of these large DNA molecules (up to 1.5×10^9 daltons) but also the fraction of the total DNA which they represent. Though the large molecular weights found were fully consistent with the hypothesis that the DNA is packaged and only cleaved once the preformed head is full, without the need for any other size determining mechanism, the presence of about 95% of the DNA in the largest heads in smaller pieces means that the evidence is not conclusive against some additional mechanism.

Host cell membrane

Another interesting area of the interaction of T4 with its host cell is the involvement of the host cell membrane in the assembly of the phage heads. It has been known for some time that the head proteins are associated with this membrane and that this association is mediated through the phage protein P31 (Laemmli *et al.*, *J. molec. Biol.*, **47**,

69; 1970), but also mutant *E. coli* have been isolated which although permitting phage absorption will not support virus production (reviewed by Wood *et al.*, *1st John Innes Symp.*, 25; 1972). In one particularly interesting 'host defective' mutant cell line it has been found that the phage heads made are apparently normal, yet they are not filled with DNA and the rate of phage DNA synthesis is abnormally low (Simon *et al.*, *Nature*, **252**, 451; 1974). Two phage mutants have been isolated, which are able to overcome this block, and one of them is again in protein P31. Further evidence that the blocking may be due to alteration of the host cell membrane comes from the observation that it could be overcome by very low concentrations of chelating agent, which have their primary effect on the

bacterial membrane.

These results suggest that the host cell membrane plays a major part in the phage DNA synthesis. It also seems to have another, and rather less obvious, function during the disruption of the host cell DNA which follows infection by T4. This occurs by a dispersal of the host nucleoid with the association of the DNA with the cell membrane and its subsequent hydrolysis. Two 'nuclear-disruption deficient' phage mutants have now been isolated, which fail to cause this association although the host DNA does still slowly disperse throughout the cell and is hydrolysed normally (Snustad and Conroy, *J. molec. Biol.*, **89**; 663; 1974; Snustad *et al.*, *J. molec. Biol.*, **89**, 675; 1974). After comparing the DNA hydrolysis and release in various endonuclease-deficient mutants

Reversals through time

from D. H. Tarling

SEVERAL recent letters to *Nature* show increasing interest in the possible causal relationship between changes in climate and changes in the intensity of the Earth's magnetic field. Such correlations, if substantiated, would explain the extinction of various marine microorganisms at times of geomagnetic polarity reversal as, at such times, the Earth's field drops to about one-fifth of its usual value. The occurrence of polarity transitions during geological time is therefore of biological and climatological interest as well as being critical to models for the generation and evolution of the geomagnetic field.

The difficulty in studying such polarity reversals is that they are brief, lasting for some 10^3 to 10^4 years, in contrast to constant polarity periods which persist for up to 50 million years. This brevity makes them difficult to study as sedimentation in the deep oceans is too slow and lava eruption is too spasmodic to permit detailed palaeomagnetic studies, except in rare situations such as where the changing magnetic vectors have been trapped during the slow cooling of a large intrusive body. Even so, the average features of reversals during the last 70 million years are fairly well known and the pioneer studies of van Zijl *et al.* showed that their properties are similar to those of a reversal some 160 million years old in South Africa (*Geophys. J. R. astr. Soc.*, **7**, 169-182, 1962).

Some 2,000 years before a change in direction, the geomagnetic field intensity decreases by 80%, after

which the direction takes about 3,000 years to reverse and is followed by 2,000 years during which the intensity returns to its usual value. It is unlikely that the time scales of individual transitions differ from such generalised figures by more than an order of magnitude and the sequence seems to be consistent. Similar changes with similar time scales also occur during geomagnetic 'events' when the geomagnetic pole seems to topple, but then returns to its previous polarity without a true reversal having occurred.

These short time scales indicate that reversals must result from short-lived geophysical processes at the core-mantle interface. The identification of generally similar features during a polarity reversal some 1,600 million years ago, as described by Bingham and Evans on page 332 of this issue, is critical to geomagnetic climatic and evolutionary models. But it also has implications for the evolution of the interior of the Earth as a whole. Since essentially identical processes seem to have been involved at the core-mantle interface in mid-Precambrian times the basic parameters of the Earth, such as the dimensions and composition of the core and lower mantle, cannot have changed significantly since then. Hence it seems unlikely that any substantial differentiation can have taken place within the mantle within the last 2,700 million years (since Archean times), and convection in the mantle since then would, therefore, have to have been shallow.

of both the wild type and the nuclear-disruption deficient phage, these authors put forward a model for the nuclear disruption process. They suggest that the host DNA becomes attached to the cell membrane at several hundred sites during a normal infection. In an uninfected cell it might be attached at about five sites—the origin and terminus of replication and a few replication forks—while in the nuclear-disruption deficient infected cells it is probably attached at fewer than ten sites. Surprisingly, in spite of this major change in the effect of the phage on the host cell DNA, no difference was detected in either the burst size or the growth rate of the mutants and the wild type.

These various results show that the growth and assembly of T4 is still a subject of considerable interest and give hope that some of the intriguing problems may be cleared up soon.

Poly(A) tales

from Tim Hunt

THE November issue of the *Proceedings of the Academy of Sciences of the USA* contains an elegant demonstration that the poly(A) tail of globin mRNA is unnecessary for its translation in cell-free protein synthesising systems. Sipple *et al.* (Columbia) (71, 4635; 1974) hybridised globin mRNA with oligo(dT) and then attacked the hybrid with RNase H, a nuclease that specifically digests the RNA strand of a DNA-RNA hybrid. After this treatment, the reaction mixture was passed over a mixed gel filtration and nitrocellulose column to remove the oligo(dT) and undigested hybrids. The mRNA that resulted was shown to be free of poly(A) by its failure to form dsRNA with ³H poly(U).

It would be hard for these authors to be sure that they had removed literally all the poly(A); the possibility that a few residues remain would not, I think, be excluded. Nevertheless, this method for removing the poly(A) has advantages over the use of polynucleotide phosphorylase or the 3' exonuclease from eukaryotic nuclei. These exonucleases are processive enzymes—they do not leave their substrate until it is completely digested; hence, in order to digest all the molecules in a message preparation a molar excess of enzyme must be added, which in turn means that it must be highly pure. In addition, it is hard to stop the enzyme from going past the poly(A) stretch into the structural mRNA. Lastly, the RNase H method has a universal application for the removal of specific pieces of RNA if the complementary piece of DNA is available.

So what happens when you remove poly(A) from mRNA? The answer is generally agreed to be almost nothing. As a template for globin synthesis in cell-free systems (wheat germ, Krebs II ascites extracts, Schreier and Staehelin) the deadenylated mRNA is just as active as its unassaulted parent. This conclusion has been reached before by Williamson *et al.* (*Biochemistry*, 13, 703; 1974), Bard *et al.* (*Cell*, 1, 101; 1974) and Soreq *et al.* (*J. molec. Biol.*, 88, 233; 1974), all of whom used processive exonucleases to remove the poly(A); Williamson *et al.* and Bard *et al.* clearly did some damage to the mRNA beyond removal of the poly(A), but Soreq *et al.* used highly purified enzyme under very restrictive conditions, and their data are extremely similar to those of Sipple *et al.*

They did notice that the activity of the deadenylated mRNA tailed off earlier than that of the native mRNA, although the effect is not dramatic. Sipple's group also report a lowered stability *in vitro*, but the cell-free system itself loses a lot of activity over the same period of time, and the decay of the message has curious linear kinetics which is unusual; normally mRNA decays exponentially. In any case, it may be dangerous to argue from cell-free experiments to the situation within living cells, and with this caution in mind, Soreq's group arranged for their mRNA to be injected into *Xenopus* oocytes (Huez *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, 71, 3143; 1974). They found that both the activity and the stability of the deadenylated mRNA were apparently impaired. I think there are problems in the interpretation of these kinds of experiment, although the experimental data are impressive. The trouble lies in knowing how to quantify the amount of protein formed after injection of mRNA, owing to uncertainties about the degree of penetration of label and its dilution with endogenous amino acids. Huez *et al.* take as their measure a comparison between radioactivity in the 'endogenous' proteins and that in the peak of globin from a gel filtration column. The tacit assumption that the rate of endogenous protein synthesis is constant is very hard to test, and may not be correct.

Interesting and pertinent studies of the stability of RNA after its injection into oocytes have been made by Allende, Allende and Firtel (*Cell*, 2, 189; 1974). They injected radioactive RNA and followed the fate of the label rather than the stability of the template activity of the mRNA. They found that the RNA was degraded at an appreciable rate, except in the cases of tRNA and poly(A) itself; however, the decay of mRNA followed biphasic kinetics. This apparently results from the interaction of mRNA with cellular com-

ponents, possibly ribosomes, since the stable fraction is not seen in the presence of puromycin. These are provocative findings in the light of the extreme stability of the translational capacity of injected globin mRNA (Gurdon, Lingrel and Marbaix, *J. molec. Biol.*, 89, 539; 1973) and also of the fact that oocytes contain respectable amounts of stored mRNA which survive from oogenesis to fertilisation (Adamson and Woodland, *J. molec. Biol.*, 88, 263; 1974). The mechanisms ensuring on the one hand the stability of these messages, and on the other their unmasking during development are quite obscure. There were certainly no indications in Allende *et al.*'s experiments that the poly(A) played a part in the stabilisation of the injected messages; it would be interesting to repeat these experiments with radioactive globin mRNA with and without its poly(A), not an easy thing to arrange except by iodine labelling, since very high specific activities are necessary.

Taken together, these experiments suggest that removing the poly(A) may reduce the stability of the mRNA in certain circumstances; but there is little evidence from studies on intact cells to support the hypothesis that a long stretch of poly(A) confers a long life on a message. Although the poly(A) gets shorter with age (Sheiness and Darnell, *Nature new Biol.*, 241, 265; 1973), it seems that old messages have a similar life expectancy to young ones in view of the well established exponential decay of mRNA (see for example Brandhorst and McConkey, *J. molec. Biol.*, 85, 451; 1974). The recent description of mRNA which lacks poly(A) in HeLa cells (Milcarek, Singer and Penman, *Cell*, 3, 1; 1974) includes data on its lifespan, and there are no indications of anything unusual about the non-adenylated species compared with the adenylated. The poly(A) of mRNA still seems to be more of a natural gift to the molecular biologists than an essential component of mRNA. Yet the refrain is always: 'It's there, so it must do something'.

Histamine and the brain

from a Correspondent

AT a meeting of the Collegium Internationale Neuropsychopharmacologicum in Paris last July, ideas about the meaning of histamine in the brain were brought together and aired (*J. Pharmac. (Paris)*, 5, Supp. 1, 69; 1974). From this airing, it emerged that histamine is present in the brain, although in smaller amounts than are its relatives, 5-hydroxytryptamine and noradrena-

line. The histamine is partly in mast cells, but partly also in nerve terminals. It is distributed unequally in the various regions of the brain, the region richest in histamine being the hypothalamus, within which different nuclei have widely different contents. The L-histidine decarboxylase that produces the neuronal histamine is also present and achieves a rapid rate of histamine synthesis, naturally followed by rapid breakdown. In experiments in which mechanical lesions were made in the medial forebrain bundle (an area associated with reward), a decrease of the histamine content and of its synthesising enzyme suggested that a tract of histaminergic fibres had been severed. All this evidence, much of which can also be found in a well-documented paper by M. Garbard and colleagues (*Science*, **186**, 833; 1974), encourages the belief that histamine should be added to the list of putative mediator or modulator substances involved in brain function.

One of the best ways of deciding whether a putative mediator is a really serious candidate is to study the effects of its specific antagonists. Such tests, with the classical anti-histamines, whose development was started by Daniel Bovet and colleagues before the second World War, have clearly indicated that histamine plays a part in anaphylactic bronchoconstriction in the guinea pig and in nasal and dermal allergy in man. This criterion also suggested that histamine might be involved in such central nervous activities as wakefulness and motion sickness, because conventional anti-histamine drugs have sedative, hypnotic and anti-emetic properties.

These anti-histamines, however, failed in several directions in which they were at first expected to act; for example they did not inhibit gastric secretion induced by histamine. This difficulty led to the recognition of H_1 and other (later called H_2) receptors (Ash and Schild, *Br. J. Pharmac. Chemother.*, **27**, 427; 1966) and to the development of antagonists for the H_1 receptor and agonists for both types of receptor that were selective to the point of specificity (Black, Duncan, Durant, Ganellin and Parsons, *Nature*, **236**, 385; 1972).

As so often happens, the availability of a specific receptor antagonist enables the action of the agonist to be clarified. In this issue of *Nature*, Baudry, Martres and Schwartz (page 362), report some insights gained from using specific H_1 and H_2 receptor antagonists (mepyramine and metiamide respectively) and an H_2 agonist (4-methylhistamine) to analyse the mechanism whereby histamine stimulates cyclic AMP formation in slices of guinea-pig cerebral cortex, an effect first observed

some years ago in rabbit cortex by Kakiuchi and Rall (*Molec. Pharmac.*, **4**, 379; 1968). The study of Baudry and colleagues shows that histamine acts on both H_1 and H_2 receptors to stimulate cyclic AMP formation, because it is not until both types of receptor are blocked that the effect of histamine is

obliterated. This finding fits with clinical experience, in that the central nervous effects of antihistamines of classical type are usually evident, but seldom intense. It would be interesting to know whether both H_1 and H_2 receptor blockers, given together, would produce profound sleep.

Cracking the genetic code is peanuts

from A. S. Craig and K. L. Giles

Genetic material of bacteroids in peanut root nodules, showing the only message de-coded to this date. Magnifications various.

DURING a study of the fine structure of root nodules from peanut (*Arachis hypogaea*) some features of considerable interest have been found. Routine electron microscope preparations of nodule tissue revealed plant cells full of large spherical bacteroids whose nuclear (genetic) material stained unusually heavily.

It did not pass our notice that the form of the genetic material in section often took on the appearance

of letters of the Roman alphabet. Armed with a knowledge of the genetic code one might have expected to find only the letters A, C, G and T. But so many were the letters found that it was possible to place several interpretations on them, one of which is shown. On these preliminary findings we are preparing a model of the genetic code based not so much on the idea of a macromolecular databank, as on a form of sophisticated semaphore.

- The use of specific H_1 and H_2 antagonists to analyse brain histamine action has been carried also into another phylum. Recently, Nahorski, Rogers and Smith (*Br. J. Pharmac.*, **52**, 121P; 1974) in experiments carried out in the cerebral hemispheres of the chick, *in vivo* and *in vitro*, found that H_2 receptor antagonists blocked histamine-induced cyclic AMP formation, whereas an H_1 antagonist was ineffective. Thus, the chick may differ from the guinea pig in that histamine receptors on its cortical adenyl cyclase may be largely of H_2 type, whereas in the guinea pig both types seem to be represented.

Glassy crystals

from Robert W. Cahn

In his stinging attack on Plato's political philosophy, Karl Popper (*The Open Society and Its Enemies*, chapter 3; Routledge, 1945) castigates Plato's "methodological essentialism", the delusion that to seek, by defining it, the essence of a thing can be a valid way of arriving at knowledge about the external world—including the world of social relations. Popper assures us that a true scientist always steers clear of questions which tempt him to definition-mongering, such as "What is an atom?" I am not at all sure that this is universally true: a passion for definitions sometimes provokes a scientist into a programme of experimentation which he might otherwise never have undertaken. The quest for the word provokes the deed.

These reflections are aroused by an unusual paper on the glassy state (Suga and Seki, *J. Non-Cryst. Solids*, **16**, 171; 1974). The authors, chemists at Osaka University, consider various ways of making non-crystalline solids other than by supercooling of a liquid, and ask whether it is plausible to call such solids "glasses". By itself, such a question deserves all the obloquy that Popper would direct upon it; but Suga and Seki went on to point out that the existence of a glass transition temperature is the crucial characteristic that has gradually come to be the defining criterion for glassiness. Thereupon they were moved to undertake a systematic study of glass transitions in a number of pure compounds nudged into non-crystalline states by cooling the melt, by condensing the vapour or by other more unorthodox means. In the course of these studies, performed in specially designed precision calorimeters (DTA apparatus), the authors discovered a number of anomalies: one compound might show more than one glass transition, and the concept of glassiness therefore required subdivision. It is rather as though St Thomas Aquinas

had conducted microscopic observations on the creatures cavorting on his needle-point and decided that it was necessary to distinguish archangels from mere angels.

Apart from a number of simple organic compounds such as isopentane, methanol, isopropylbenzene and cyclohexanol, the authors also examined a number of inorganic and organic high polymers, some inorganic materials (H_2O , $SnCl_4 \cdot 2H_2O$) and a range of compounds that form nematic or smectic (liquid crystal) phases. Thirty-eight materials were studied.

With regard to many of the simple compounds, it turned out that ordinary glass transitions, in the form of anomalies in the specific heat, turned up irrespective of whether the non-crystalline forms were prepared by supercooling a liquid, by condensation from the vapour or by rapid precipitation from solution. This answered the original question.

But three kinds of anomalous glass transitions were also found in some materials in addition to the ordinary transitions. Some compounds (for example, cyclohexanol, 2,3-dimethylbutane) have been known for some time to possess an intermediate structure at temperatures between full crystallinity and full liquidity, the so-called 'plastic crystal' state. The molecules are positionally ordered but orientationally disordered and mobile. This makes the molecules dynamically pseudo-spherical; because of this, they crystallise in face-centred cubic or body-centred cubic structures, which are unusually prone to plastic deformation: hence the name. Suga and Seki found that by rapid cooling they were able to freeze in this anomalous state, which they christened glassy crystal; on gradual reheating, the metastable glassy crystals passed through a 'glass transition' at which the metastable form transformed irreversibly into a fully ordered crystalline polymorph.

Another form of glassy crystal was found by supercooling of water, $SnCl_4 \cdot 2H_2O$ or $SnCl_4 \cdot 2D_2O$. Here the partial disorder was attributed to a freezing-in of the irregular positions of protons or deuterons; in this connection, the different transition temperatures for the last two compounds were of particular interest. There is a particularly full historical discussion of glassy ice—which, incidentally, has nothing whatever to do with the notorious polywater of a few years ago!

Finally, Suga and Seki examined a number of liquid crystals, in which there is orientational order, accompanied by positional disorder of molecules. It proved possible to 'freeze' this state by rapid cooling. The steady variation with temperature of the degree of molecular alignment, in the

'swarms' which are the liquid-crystal equivalents of ferromagnetic domain is thereby inhibited. When the glass liquid crystal, as the authors call the state, is heated through a transition the molecules regain their labile ability to vary their degree of alignment.

Two compounds—cyclohexene and ethanol—were found to possess two anomalous transitions each as well as a normal transition. The nature of the two anomalous glassy crystalline states is not yet known.

The authors document their findings not only by locating glass transition entropy with temperature: from these plots they are able to make further deductions about the nature of the change they have observed.

The concept of a glassy crystal was sometime a paradox, but now the tin gives it proof. Suga and Seki's paper is an impressive achievement which should stimulate many structural studies to confirm and extend their bold but sometimes tentative interpretations. Such studies may also have bearing on topochemical reactions (see the detailed and very instructive review by J. M. Thomas, *Phil. Trans. R. Soc.* **277**, 251; 1974). Topochemistry is concerned with the nature and kinetics of chemical reactions, including polymerisation reactions, between adjacent molecules in crystals, and such processes are bound to be modified if the state of positional and orientational order of molecules can be varied as then frozen into a particular pattern. Perhaps compounds can now be found in which internal reaction mechanism will change at glass transition temperatures. If this proves to be so, we shall need a new definition to denote the process: vitrochemistry, perhaps!

Behaviour in Europe

from a Correspondent

THE first European Neuroscience meeting will be held in Munich next September (for details see the advertisement on page vii). This meeting represents the culmination of several years' effort to promote collaboration between workers in different European countries and in different disciplines within the field of brain and behaviour research. The meeting is organised by the European Training Programme in Brain and Behaviour Research (ETP), a body whose history is of some interest.

In 1968, the Organisation for Economic Cooperation and Development inaugurated studies of three scientific fields: the criteria for selecting fields were that they should be multi-disciplinary, have a fast growth rate, have insufficient recognition, an

Climbing the technology tree

from Andrew Holmes-Siedle

THE Institute of Electronic and Electrical Engineers, one of the largest professional societies in the world, has turned some of its effort to helping those scientists and engineers faced with redundancy to plot their careers in such a way that they avoid the trap of 'irrelevance'. Its Technology Forecasting and Assessment Committee, whose original purpose had been to advise industry and government on planning, has now turned all its attention to an advanced form of career guidance. The committee has picked areas of application for which technology is being developed intensively and drawn

for each a 'technology tree' which relates these areas logically and lists the technologies involved in each.

To give an example, the Nuclear and Plasma Sciences Tree (Published in the IEEE Nuclear and Plasma Sciences Society Newsletter, October 1974) carries a limb entitled 'Radiation Effects' which contains eleven branches with 43 twigs, the subjects ranging from charge loss in capacitors to food preservation. To put it another way, the IEEE has identified some technological bandwagons and given us a few clues as to how we might climb on, the rest is up to us.

be likely to produce results both of scientific and practical importance within a decade. One of the fields chosen was Brain and Behaviour and in 1972 OECD published a report with this title prepared by two of its consultants, Dr Otto Wolthuys and Professor Stuart Sutherland. The report summarised the scientific status of the field and analysed a number of defects in its organisation in Europe including Britain. Among the defects mentioned were the lack of mobility of scientists, resulting in a slow flow of ideas and parochial journals, lack of communication between European countries, small laboratories with insufficient interaction between, for example, neurophysiologists and psychologists, and authoritarian departmental structures.

The OECD investigation led in 1970 to the setting up of ETP with a generous grant from the Max-Planck-Gesellschaft. It now receives contributions from Austria, Britain, France, Germany, Italy, Netherlands, and Switzerland and seven additional countries have representatives on the steering committee and participate in the programme. So far funds have been used for the following purposes:

- The training of young scientists in countries other than their own and usually in disciplines other than their primary subject
- Four highly successful winter schools for young scientists from all European countries—again with a multi-disciplinary emphasis
- 'Twinning' grants awarded to about 100 laboratories, enabling the members of each to travel to a sister laboratory abroad which is engaged on complementary work
- Grants enabling young scientists to attend conferences abroad organised by bodies other than ETP

In the five years of its existence ETP, operating on an insecure budget of about £50,000 a year, has done much to promote cooperation between workers in brain and behaviour in different European countries and in the different component disciplines. It is hoped that when the European Science Foundation starts functioning ETP will become affiliated, and that a more permanent flow of funds will be secured through international treaties. Unlike EMBO, ETP has set its heart against the founding of a large international laboratory since it is thought that the centralisation and bureaucracy involved are not in the best interests of the subject.

High-pass phonon filter

from P V E McClintock

SUPERFLUID 'He can be made to act as a tunable high-pass phonon filter, according to some recent experimental work at Nottingham University by Wyatt, Lockerbie and Sherlock (*Phys Rev Lett*, **33**, 1425, 1974).

Their experiment was performed below 0.1 K, where liquid 'He is an almost pure superfluid, that is, a fluid which can indulge in frictionless flow, or through which objects can move without any dissipation of their kinetic energy. The superfluid itself carries no entropy, but acts as the inert background or aether supporting a gas of phonons, which are the quanta of vibrational energy. These behave much like a collection of independent particles moving at the velocity of sound, and they carry all the thermal energy of the liquid.

The Nottingham experiment consisted, essentially, of injecting relatively

small numbers of very high energy phonons into the superfluid at temperatures below 0.1 K, investigating how they propagated through the liquid and, in particular, deducing whether they were able to decay. (Strictly, of course, the term 'temperature' is not applicable once the high energy phonons have been injected, because there then exists a non-equilibrium situation.)

Considerable interest attaches to whether or not a phonon of given initial energy is able to decay into two phonons of lower energy, since this yields direct information about the shape of the dispersion curve, that is, the relationship between a phonon's energy ϵ and its momentum p . It was long believed that for small ϵ the dispersion curve was linear, of the form $\epsilon = cp$ where c is the phonon velocity in the long wavelength limit, but that at higher ϵ the curve deviated below cp (negative dispersion), representing smaller phonon velocities. More recently, mounting evidence has apparently indicated that, although the dispersion curve is indeed linear at very small ϵ , there is an intermediate regime in which it deviates upwards (positive dispersion) before entering the negative dispersion region.

The precise shape of the dispersion curve is of considerable importance because of its profound influence on 3-phonon processes, that is, the decay of one phonon into two of lower energy or, conversely, the combination of two low energy phonons to create one high energy phonon. Such processes are of crucial importance in determining many of the properties of the liquid, such as the ultrasonic attenuation or the normal fluid viscosity, at temperatures near 1 K. It turns out that for 3-phonon processes it is only possible to satisfy simultaneously the conservation of energy and momentum in the presence of positive dispersion: the interactions cannot therefore occur at all where the dispersion is negative. Unfortunately, it is difficult to deduce the shape of the dispersion curve unambiguously from, for example, normal fluid viscosity measurements near 1 K. This is partly because phonons of a very wide range of energies are simultaneously present, but also because of complications arising from the existence at these relatively high temperatures of large numbers of rotons, which are another type of thermal excitation.

Hence the value of performing experiments at very much lower temperatures where the thermally excited 'background' phonons are so few that they can be neglected. The Nottingham group used a superconducting fluorometer to inject into the liquid pulses of phonons which all had energies larger than 2Δ (Δ being the energy gap of the superconductor), and detected

the phonons again after they had travelled several mm through the liquid with a superconducting tunnel junction, a device which is sensitive only to phonons of energy greater than 2Δ . Thus, the decay of an injected phonon would have yielded two phonons each of whose individual energies would have been too small to be seen by the detector, so that the observed attenuation of the phonon pulse could be regarded as a direct measure of the extent to which 3-phonon decays had occurred during the transit.

The main experimental finding was that the number of phonons reaching the detector depended strongly on pressure for pressures from 0 to 13.5 bar, but was almost pressure independent from 13.5 bar right up to the solidification pressure of 25 bar. The effect could not be due to changes in the number of high energy phonons generated in the fluorescer, since the performance of these devices is independent of pressure. There appeared to be two possible explanations: (1) some sort of dissipative effect occurring in the bulk of the liquid, attenuating all phonons, or (2) because of positive dispersion, the injected phonons might have been able to decay by 3-phonon processes, resulting in phonons of insufficient energy to stimulate the detector.

The first hypothesis was rapidly disposed of by altering the separation of the source and detector. The pressure dependence of the detector signal was quite independent of the separation, thus ruling out possible bulk attenuation effects.

The authors therefore conclude that the second hypothesis is the correct explanation. They suggest that there is a critical phonon energy ϵ_c below which a phonon decays rapidly, but above which a phonon will be stable and therefore able to travel long distances through the liquid. If ϵ_c decreases with increasing pressure, and if at 13.5 bar ϵ_c is equal to the minimum injected phonon energy of 2Δ , then the experimental data can all be understood. At higher pressures ϵ_c would become smaller than the lowest energy phonon from the fluorescer and the injected phonons would therefore all reach the detector without decaying, thus accounting for the observed pressure independence of the signal above 13.5 bar.

The scenario proposed by the authors is therefore as follows. When a pulse of phonons with an initially wide range of energies is injected into the superfluid, those phonons with energies less than ϵ_c decay almost immediately owing to the existence of positive dispersion, whereas those with higher energies, in the negative dispersion regime, propagate freely. Thus the liquid acts as a

high pass filter, passing only phonons of energy above ϵ_c . Because ϵ_c can be changed by altering the pressure, the filter is tunable and clearly has possible applications in the growing field of phonon spectroscopy.

This rather novel picture of liquid helium is certainly consistent with existing experimental information, but it is to be hoped that the authors will now carry out further checks on its veracity, in particular by repeating the experiments using detectors sensitive to a number of different phonon energies.

Structure and dynamics of spiral galaxies

from Vincent Icke and James Pringle

On Thursday, January 9, an informal discussion day at the Institute of Astronomy, Cambridge, brought together some 50 astronomers from various parts of the UK, to exchange news and views on the structure and dynamics of spiral galaxies.

BARRY MADORE (IOA, Cambridge) reviewed the situation nearest home, showing how the spiral structure of our Galaxy in the neighbourhood of the Sun can be determined by 'spiral tracers'. These are young, massive bright stars which, since star formation takes place predominantly in spiral arms, serve as 'standard candles' to delineate spiral structure out to distances of about 15,000 light years. Observing at Cerro Tololo, Madore has concentrated on the Northern Hemisphere which thus far has received only thin coverage. His results on the distances of classical Cepheids has extended the known nearby spiral pattern, but more observations are still required.

Passing to external galaxies, Greg Davidson (Jodrell Bank) and Darrell Emerson (Mullard Radio Astronomy Observatory, Cambridge) presented observations of the rotation speed and the neutral hydrogen distribution of the Andromeda Nebula M31. The dependence of the rotation speed on radial distance indicates the mass distribution in a galaxy. Davidson found that in the outer regions of M31, the rotation curve is flat, indicating a very large amount of mass in the 'halo' of this galaxy. The results, however, are not yet clear cut because the low resolution of the Jodrell Bank Mk I telescope tends to smear out and flatten the rotation curve. Emerson's observations of the disk showed ridges of condensed gas around the centre of M31,

forming rings or spiral arms (this galaxy is seen too edge on to enable one to say which of these two alternatives is the better). The velocity field, mapped by observing the Doppler shifts of the 21 cm hydrogen line, shows distinct non-circular motions, perhaps indicative of the motions which theorists predict for the gas condensations as spiralling density waves propagating through the disk. But here too the galactic inclination makes it impossible to distinguish between spiral and ring-like structure.

An alternative to density waves as the cause of spiral structure is the possibility that spiral arms are formed by galactic 'tides', generated by a previous close encounter of two galaxies. Observational evidence for such encounters was given by Anthony Winter and Geoffrey Cottrell (MRAO, Cambridge) who have respectively studied the pairs NGC9631-9656 and M81-NGC3077. An extensive neutral hydrogen complex is found to surround the spiral galaxies NGC9631-9656. From the velocity structure of the complex it is apparent that the gas actually links the two galaxies, the velocities in the gas match those of the galaxies and show a systematic trend from one to the other, thus linking them in 'velocity space'. Although the observations clearly show that the encounter profoundly disturbs each member of the pair, the influence on spiral structure is unknown because both galaxies are seen edge on. The pair M81-NGC3077 is more promising in this respect. M81 is one of the most beautiful two-armed spiral galaxies known. In this case, however, the evidence for tidal interaction is less strong. NGC3077 possesses a comma-shaped hydrogen extension, pointing towards M81, and this 'tail' may be a remnant of a hyperbolic encounter about 10^9 yr ago.

A hundred years ago

IN reference to the proposed Channel Tunnel between France and England, we may refer our readers to *NATURE*, vol 1, pp 160, 303, 631, and vol x, p 181, where the scientific bearings of the subject are pretty fully discussed. While on this matter we may state, on the authority of *La Nature*, that there has been in existence for some time in Spain an Inter-continental Railway Company, whose object is to connect Europe and Africa by a tunnel underneath the Straits of Gibraltar, the maximum depth of which is 819 metres from *Nature*, 11, 273 February 4, 1875.

To understand the large-scale motions in galaxies it is important to know how they interact with their surroundings. An aspect of this was studied by Roland Hunt (University of Oxford) who presented theoretical calculations of the effects which the infall of intergalactic gas would have on our Galaxy. The main consequences are a slow inward streaming of gas in the galactic plane and a peculiar relationship between the chemical composition of stars and their ages. The observational data are consistent with the no infall of gas at all, but an accretion rate of three solar masses per year is not excluded.

James Binney (University of Oxford) discussed a problem which has confronted theorists almost since the discovery of external galaxies, namely the origin of their considerable angular momentum content. In a universe which is initially homogeneous and isotropic (as ours appears to be) vorticity must somehow be generated. Binney has considered the creation of vorticity by the shock fronts which probably accompany the early stages of contraction of clusters of galaxies. It seems possible to account for the rotation of spiral galaxies, but the model may be rather sensitive to the shape of the shock fronts.

For simplicity, most theorists assume that the motions in a spiral galaxy can be satisfactorily simplified to motion in an infinitesimally thin disk. Douglas Heggie (IOA, Cambridge) presented some surprising results which indicate that one should be wary of such implications. He finds that, contrary to earlier expectations, the gravitational potential of a spiral wave can excite stars into resonant orbits perpendicular to the galactic plane. This drives stars far away from the plane, giving the disk a definite thickness. Resonance of the stellar orbits with the spiral pattern can then interfere with the propagation of spiral waves.

How a spiral wave might persist with a constant amplitude over the $\sim 10^{10}$ years' lifetime of a galaxy was discussed by Vincent Icke (IOA, Cambridge). He presented a wave equation in which energy losses and dispersive effects are counteracted by nonlinear terms, so that some wave solutions maintain the same amplitude indefinitely. Analogous equations in hydrodynamics and plasma physics exist which also exhibit these solitary waves or 'solutions'. Finding two-dimensional solutions, however, seems difficult.

Bernard Schutz (University College, Cardiff) presented calculations of the normal modes of instability of a galactic disk. In this type of analysis, the solution of Poisson's equation for the gravitational potential and of Vlasov's equation for the velocity distribution of the stars present formidable

obstacles. These were side-stepped by exploiting the thinness of the disk to approximate the gravitational potential by a polynomial series, and by treating the disk as a fluid. It is found that the fastest growing mode is a very open spiral, trailing with respect to the galactic rotation.

A computational approach to the origin of spiral structure was made by David Brownrigg (University of Reading), who used a cell-averaging technique to calculate the three-dimensional motion of 25,000 particles with mutual gravitational attraction. These particles represent Population I disk stars moving in a spherical potential corresponding to the average gravitational field of the Population II halo stars. The model seems to be a fair representation of a self-gravitating collisionless point-particle system. The model galaxy exhibits some impressive density-wave type spiral structure in its outermost parts.

Present thinking on the problem of galactic spiral structure was clearly reflected in the emphasis which the participants in the discussion put upon the observation of noncircular motion in single galaxies and of interacting galaxies, and in the preoccupation of most theorists with instabilities and wave propagation in differentially rotating disks. It seemed to be generally felt that progress in the understanding of spiral galaxies will be conditional upon the progress in these fields.

Identifying ancient forest

from Peter D Moore

THE climatic climax vegetation of England and Wales is generally considered to be deciduous forest, yet, as a result of human interference since prehistoric times, little, if any, woodland with an uninterrupted history now remains. It is natural, therefore, that conservationists should be concerned with devising methods by which fragments of ancient forest can be identified in order to protect them from further damage. The most useful criteria so far employed as indices of antiquity are the general species density of the habitat and the presence of species which are sensitive to disturbance.

Species richness is a concept which was touched upon recently in these columns when its relationship to time was considered (*Nature*, 252, 14, 1974). Southwood (*J anim Ecol*, 30, 1, 1960) demonstrated a positive correlation between subfossil abundance of British tree species and the number of associated insect species. He also demonstrated from Hawaiian data (*Proc*

Hawaiian ent Soc, 17, 299, 1960) that a general relationship exists in which the more abundant trees have higher numbers of associated insects. It is reasonable to expect, therefore, that assemblages of tree species which have occupied extensive and uninterrupted areas over considerable periods should support a rich insect fauna. It would seem reasonable also to extend this argument to associated plants and to use, for example, the richness of epiphytic bryophyte or lichen flora or of understorey herbs as an indication of old forest.

Rose and James (*Lichenologist*, 6, 1, 1974) have recently studied the lichen flora of the New Forest in southern England. This ancient Royal Hunting Forest contains wooded areas which have remained forested at least since mediaeval times and probably for even longer. The epiphytic lichen flora of the forest was found to be exceptionally rich, 259 taxa being recorded during the intensive six-year survey. Species density in some areas is as high as 160 km^{-2} which is a figure exceeded only in some extremely oceanic woodlands in the western extremities of Britain (Rose, in *The British Oak, Its History and Natural History*, edit by M G Morris, and F H Perring, 258, Classey, Farrington, 1974) where climatic factors are particularly suitable for epiphyte growth. It appears, therefore, that epiphyte species density can provide some measure of the historical continuity and lack of fragmentation of a forest.

The richness of the epiphyte flora of the New Forest cannot be explained simply in terms of the tree species available as hosts. Many epiphytes are selective with respect to host species, being particularly sensitive to the physical and chemical nature of the host's bark. Rose has determined the number of epiphytic lichens associated with various tree species and they fall in the order oak (303), ash (230), beech (194), elm (171) and sycamore (170). The New Forest contains mainly oak and beech, but the other epiphyte-rich tree species are rare or absent. Since oak/beech forest is common in southern Britain, the richness of the New Forest is best explained in terms of its historical continuity and also the low levels of atmospheric pollution experienced.

It is interesting to note in passing that the richness of Rose's epiphytic lichens is not related to the age or to the area of trees, or both, in the way that Southwood has demonstrated for insects. Some of our more ancient and widespread trees, for example, have a far poorer epiphyte flora than those mentioned above, such as birch (93), hazel (124) and alder (72). Southwood has suggested that an abundant tree is

more frequently encountered by an insect and that this assists the development of a feeding relationship. This process does not seem to have been generally operative in the case of the host/epiphyte situation during the post-glacial period in Britain.

Species density alone, therefore, may indicate antiquity in a forest, but it may also be misleading under certain conditions, for example, the increased microhabitat diversity which accompanies limited disturbance may, at least temporarily, inflate species density since it allows the invasion of species characteristic of unstable habitats. Also, local air pollution may deplete the epiphyte flora of even an ancient forest. A more hopeful approach to the assessment of past forest continuity is the use of species which are sensitive to disturbance. Rose has attempted this by constructing an "Index of Ecological Continuity" for woodlands based upon the occurrence of twenty selected lichen species which he regards as indicative of long periods of undisturbed woodland conditions. On this scale the New Forest has a rating of 100, very few other British woodlands have values of more than 70. Again, however, some woods with lengthy historical continuity could be underrated because of recent pollution, particularly in eastern Britain.

Peterken has recently proposed (*Biol Cons*, 6, 239, 1974) a similar system which he has used for the assessment of woodlands in Lincolnshire for conservation purposes. He selects flowering plants and ferns confined or almost confined to proved ancient ('primary') woodlands within an intensively surveyed study area and uses these as a yardstick for assessing woodlands over a wide region. His data demonstrate a positive correlation between the number of 'primary' woodland species recorded at a site and the area of the site. This suggests that richness in sensitive woodland understorey species is a function of undisturbed conditions in both temporal and spatial dimensions. As with the epiphytes, the oceanic conditions of western Britain are particularly favourable for the growth of woodland plants, hence some of the species indicative of antiquity in eastern Britain are more widespread in the west. Complications from air pollution, however, are likely to be less important than when using epiphytes as indicators, since understorey herbs are less sensitive.

Many of the plant species used by Rose and by Peterken as indicators of undisturbed situations grow slowly under conditions of low humidity and are poor in their dispersal capacity, thus spatial fragmentation of woodland presents them with problems of spread and survival. It is the presence of these

indicators, rather than the total number of species per unit area, which is likely to provide the clues for the detection and subsequent conservation of our dwindling fragments of ancient woodland.

Properties of plasmas

from A G Sitenko

The Second International Conference on Plasma Theory was held in Kiev from October 28 to November 1. The Conference was organized by the Institute for Theoretical Physics of the Academy of Sciences of the Ukrainian SSR and the Lebedev Physical Institute of the USSR Academy of Sciences and was sponsored by the International Union of Pure and Applied Physics.

CONTEMPORARY plasma theory is based largely on statistical methods—but there are different techniques for describing the properties of the statistical system. A G Sitenko proposed a detailed description of statistical and electrodynamical plasma properties, based on the consideration of fluctuations. Of fundamental importance in this description are the spectral correlation functions, which have simple analytical properties. In linear electrodynamics the fluctuation-dissipation theorem establishes a relation between fluctuations of different quantities and electrodynamic properties of the medium. That is why, once we know the fluctuation spectrum in plasmas, we can determine the electric plasma susceptibility by inversion of the fluctuation-dissipation theorem. The generalisation of this theorem for the non-linear case allows the description of non-linear electrodynamic plasma properties. Allowing for the non-linear wave interaction explains the saturation of the fluctuation level in non-equilibrium plasma under critical conditions. This level, corresponding to the stationary turbulent plasma state, can exceed the thermal level significantly. The kinetic equation for waves is derived, taking into account the interaction of waves with fluctuating fields in plasmas. To neglect this interaction (a procedure adopted in many papers) is not valid in nonequilibrium plasmas. In the stationary case the solution of the kinetic equation determines the fluctuation spectrum for the turbulent plasma state. Such an approach is very promising when considering the scattering and transformation of waves in plasmas.

V E Zakharov applied the inverse scattering problem method to non-

linear problems of plasma physics. He showed that a set of non-linear equations, which describes resonant interaction of three one-dimensional wave packets, may be solved exactly by the inverse problem method. The conservation laws are found and complete integrability of the equations is proved. In the case of decay resonant interaction between wavepackets the physical picture depends on the relative magnitudes of pumping rate and secondary waves' velocities. If the pumping rate is intermediate between the velocities of secondary waves, then the long packet of pumping decays practically completely when it collides even with arbitrarily small secondary wavepackets, but if the pumping rate is extreme, then the decay of the pumping wave is possible only when colliding with intense enough secondary wavepackets. The solutions for explosive instability are found, which describe the rise of local singularities in the limited wavepackets.

The question of turbulent plasma heating by beams of electrons and light was discussed by L I Rudakov on the basis of the soliton model of turbulence. The solitons may be formed as a result of a one-dimensional turbulent state modulation instability and are in fact sets of waves, trapped by the diminished plasma density domains, which, in turn, appear under the high-frequency field pressure. The formation of solitons is energetically advantageous, as it causes a decrease of the Langmuir quanta frequency, and the released energy promotes the formation of diminished density domains. As a result of collisions the solitons can decay or join. If the distances between the solitons exceed their sizes, then binary collisions play the main part. The electron changes its velocity when passing through the soliton. As a result of repeated collisions the electrons can increase their energy, thus changing the distribution function. This picture for the one-dimensional case is confirmed by the numerical integration of the non-linear equations of Langmuir turbulence. The joining of solitons can lead to the collapse phenomenon, that is, to dynamical accumulation of energy in certain regions of space. The existence of such a process, when special initial assumptions are fulfilled, is confirmed by numerical calculation. The interaction between particles and the collapsing formation causes the heating of the particles in the medium.

In conclusion, the conference gave participants a good chance to acquaint each other with investigations in plasma theory. The next International Conference on Plasma Theory will be organised by A Salam in 1976 at Trieste.

review articles

Unclocklike behaviour of biological clocks

Arthur T. Winfree*

The mechanisms which could underlie circadian rhythms fall naturally into groups with qualitatively different responses to disruption. Experiments designed to distinguish between these mechanisms seem to exclude all of them. It may be that multicellular organisms keep time, not by one 'clock' but by averaging many independent circadian oscillators.

"I hear the sound of time And yet I slew it, and
wiped my bloody sword upon its beard"¹

AN impressive diversity of organisms seems to have internalised the 24-h periodicity of this rotating planet. Exceptions include the prokaryotes, the bryophytes, most embryos and species evolved in soil, deep caves and the abyss²⁻⁶. But in most other creatures, body temperature, enzyme activity, leaf movement, neural firing, mitotic index or other convenient observables typically persist in regular up and down periods of about 24-h, even in ostensibly constant conditions²⁻⁶. These are called circadian rhythms to distinguish them from biological activities which persist in 24-h periodicity only so long as they are exposed to environmental cues at the same intervals. Brown and coworkers argue that even these circadian rhythms would stop or grossly change their period should the planet stop rotating, because they depend on the organisms sensing rhythmic fluctuations in subtle geophysical variables²⁻⁶. Although some quantities, such as the electrical charge of the atmosphere, fluctuate diurnally in synchrony around the whole planet⁷, many candidates for the role of covert driving rhythm are excluded by the persistence of circadian rhythms on a rotating platform at the south pole⁸. Though it is impossible in principle to exclude all hypothetical drivers experimentally, most workers since the 1930s⁹⁻¹¹ infer from the following generalisations that one ought instead to look for a mechanism of spontaneous oscillation within the organism.

The circadian period, though often precise to within an hour per month, seldom exactly matches the dominant periods of geophysical variables. The circadian period depends on temperature, typically drifts a few percent within one day and is chemically adjustable. Mutants of altered period exist. The phase of a circadian rhythm is labile with few exceptions (possibly including humans) it is permanently reset by a pulse of light or brief elevation of temperature within the physiological range or by temporarily withholding oxygen²⁻⁶.

Moreover, most workers seem to think in terms of an ultimately cellular mechanism, because organ and tissue-level interactions do not seem to be crucially involved.

Protozoa and unicellular algae exhibit typical circadian rhythms (for example of bioluminescence, motility, mitosis and surface antigenicity). The leaves of plants, bits of cut leaf or of cultured leaf callus independently support circadian rhythms of movement or respiration. Isolated mammalian organs and even disaggregated cells persist in

circadian variations of electrical activity, enzyme activity, respiration and so on²⁻⁶.

Attempts to pinpoint the cellular mechanism of such long-period rhythmicity have led to models emphasising cellular membranes¹⁰, cytoplasmic enzyme reactions¹¹⁻¹³, or sequential transcription of the nuclear message¹⁴⁻¹⁶. The diversity of action spectra for rephasing by light²⁻⁶ suggests a corresponding diversity of molecular mechanisms, at least at the photoreceptor end of 'the clock'.

Without wishing to deny the fascination of particular cases, I feel that a biophysical search for the unique mechanism of some universal clock is likely to be no more rewarding than earlier quixotic searches for the mechanism of 'homeostasis' or of 'excitability'. In such complex dynamical systems as living cells, stable steady-state operation can only be a result of the most intense selection¹⁷. Instabilities typically lead to spontaneous oscillation (the alternatives being some kind of semiperiodicity or unpredictable aperiodic fluctuations¹⁸). Thus the role of natural selection in adapting cells to a periodic milieu may be not to contrive and refine a timer so much as to weed out irregular fluctuations and oscillations of maladaptive period and to synchronise the rest. Such speculation discourages belief in a unique evolutionary ancestor of contemporary 'clocks'. It offers an interpretation of the curious facts that many circadian rhythms lack discernible selective value^{19,20} and that their evolution seldom if ever involved selective challenges during prolonged isolation from the environmental day/night cycle yet they cycle autonomously with precise period. It may be that the generic features of circadian rhythms stem more from convergent evolution and the common properties of complex dynamical systems than from a ubiquitous mechanism. For example, many of the peculiarities of the phase-resetting behaviour of circadian rhythms are also seen in a wide variety of electronic²¹, mechanical, and mathematical models²⁻⁶, and can be rationalised by simple topological principles without recourse either to such metaphorical models or to arguments from presumed selective advantage²².

What then can be learned by studying the phase shifts of biological rhythms? Such study leads to some 'unclocklike' aspects of whole-organism rhythmicity which were neglected so long as the "clock" metaphor, early introduced²³⁻²⁵ to emphasise the presumed significance of circadian rhythms for timing, biased investigators toward preoccupation with phase on a presumed rigid cycle. The encounter with unexpected and 'unclocklike' behaviour results from investigations into that timing role and the adaptive reasons for it.

Given the inevitable small discrepancy between the organism's circadian period and that of the environmental

*Address: Department of Biological Sciences, Purdue University, West Lafayette, Indiana 47907

Fig 1 Old phase and new phase axes each extend through 1.5 cycles of 24 h. *a*, A type 1 resetting curve (typical of 'simple clock' mechanisms and weakly perturbed limit cycle mechanisms) rises through 1 cycle of new phase per cycle of old phase. *b*, A type 0 resetting curve (typical of strongly perturbed limit cycle mechanisms) shows no net drift along the new phase axis.

rhythms of food availability, predation, warmth, dryness and so on, an occasional phase correction seems necessary to maintain any preferred phase relation. The ultimate pacemaker and most reliable indicator of environmental phase is the rising and setting of the sun, that is, the light/dark cycle. With few exceptions, circadian rhythms are temporarily deranged by visible light: when normal rhythmicity recovers, it is found to be phase-shifted relative to an unexposed control. In *Drosophila*, for example, light as dim as starlight, if prolonged, damps out the rhythm²⁶, and a brief exposure at somewhat greater intensity changes the phase by as much as half a cycle before even 1% of the pigment molecules can have absorbed a photon²⁷. (The clock pigment of *Drosophila* is not in its eyes and is not rhodopsin (refs 28 and 29 and A. T. W. unpublished).) By altering the normal light cycle in agricultural fields with dim lights³⁰ or even a single nightly photoflash³¹, the seasonal adaptations of insect pests can be lethally disrupted, presumably through circadian rhythms involved in seasonal photoperiodism^{32,33}.

To ensure stable entrainment, the phase adjustment inflicted must vary according to the original phase at exposure. Measurements of this dependence have been carried out in many laboratories investigating the cell cycle³⁴, neurophysiological rhythms³⁵⁻³⁷ and circadian rhythms²⁻⁶. Particularly in the latter cases, certain peculiar regularities have emerged which seem hard to account for in terms of natural selection, but are typical of a broad class of dynamical systems (and atypical of others). Before introducing these data it will be useful to distinguish three traditions of thinking about the mechanism of biological rhythms.

Clocks and oscillators

In the first view, the mechanism underlying overt rhythmicity is called a 'clock' or, as in the cell cycle literature, a 'simple clock'^{38,39}. Its possible states can be arranged in a recurring sequence in which each state induces the next in a repeating cycle. The "state space" is a circle and there is no state which is not represented in that space. The clocks of home and industry are of this kind, the only variable quantity in the clock is the angular position of its meshed gears, and to get to a new position, it must pass forward or backward through all intermediate positions. Virus replication constitutes such a clock, the polymerase advancing round and round a circular genome at a rate limited by substrate availability, a similar model originally proposed for the cell cycle⁴⁰ is the basis of one conjecture about the circadian mechanism in eukaryotic cells^{14-16,41}.

Much of the literature implies that 'biological clocks' are clocks in this sense, that is, that the mechanism adheres to

a one-parameter sequence of states or 'subjective circadian times'. For example the widely adopted definitions 'phase' and 'phase shift'⁴² and many analyses of the process of rephasing⁴³⁻⁴⁵ implicitly or explicitly assume that the clock is always at some phase in its cycle, with phase changing at a rate determined by light intensity and current phase. Integrating this rate function as the phase changes during an exposure, one can calculate the new phase reached as a function of old phase for a given light intensity and duration⁴³⁻⁴⁵. 'Simple clock' mechanisms are distinguished by the smoothness of this rephasing curve (Fig 1*a*), its limitation to positive slopes and the fact that its mean slope is necessarily exactly 1 (as it is, for example, in response to a vanishingly brief stimulus, following which new phase = old phase)³⁹. We call this, by the mean slope of the rephasing curve, 'type 1' rephasing: the curve rises through one cycle of new phase in each cycle of old phase as it traverses to the right.

In contrast, Kalmus⁴⁶ and Mori⁴⁷, following Bonhoeffer's treatment of electrical rhythms in cells^{48,49}, were the first to emphasise limit-cycle oscillator models for circadian rhythms. In this view two or more variables (for example chemical concentrations) smoothly affect each other's rate of change in such a way that departures from equilibrium are not opposed. Either spontaneously, or once disturbed beyond a certain threshold distance from equilibrium, such a system quickly approaches a 'limit cycle' in which both quantities fluctuate regularly, at the same period but out of phase. Disturbed from this cycle, the system quickly returns to it, amplitude and waveform are subject to vigorous regulation. Regardless of their potential complexity (for example the number of variables involved), limit cycle mechanisms differ from 'simple clock' mechanisms in the possession of easily accessible states (including an equilibrium point) from which normal rhythmicity

Fig 2 Cycles 4-8 of control rhythm event time are plotted against reset rhythm event time, both measured from stimulus time. Since event time (arrows in *a*) is the complement of phase at stimulus time, these axes are equivalent to backward old phase and new phase axes, respectively. *a*, Plot of a single experiment against its control, *b*, (arrows omitted) twelve experiments plotted, each with stimulus falling at a different phase in the control rhythm. Data represent centroids of *Drosophila* eclosion peaks, showing type 0 reset by 12,000 erg cm⁻² of blue light.

never develops, or does so at unpredictable phase after a unpredictable lag period^{49,50,51}. These phenomena are implicit in several mathematical metaphors employed by theorists of circadian rhythmicity^{52,53}. The rephasing curves of limit cycle mechanisms are not limited to positive slope and can have a mean slope of 1 or 0 (or any other integer if more than 2 variables are involved)³⁹. In 'type 0' rephasing, what goes up must come down before the curve passes one cycle of old phase to the right (Fig 1*b*).

And what about the ubiquitous relaxation oscillator model? According to this view, popular among biologists concerned with the cell cycle⁵⁴ and nerve activity⁵⁵ as well as circadian rhythmicity²⁻⁶, some photolabile metabolite accumulates until a threshold concentration is reached when it is all destroyed or a gradual destruction begins

which will be terminated at a lower threshold. Exposure to light or a temperature shock prematurely destroys the accumulated substance. Though such a mechanism may be viewed as a limiting case of a simple clock or limit cycle, it is conveniently treated separately. Its rephasing curves all have an abrupt jump whose magnitude increases with stimulus duration. Consequently 'average slope' is ambiguous.

Simple clock excluded experimentally

No circadian mechanism has been observed directly. But it is possible to measure the rephasing curves by monitoring any conveniently observable rhythm, on the assumption that a constant phase difference between an undisturbed control and the disturbed rhythm reflects the same phase difference between the circadian oscillators driving each rhythm (usually it is a few cycles before the disturbed rhythm recovers its normal period and the phase difference becomes constant). Taking the time of the rephasing stimulus as zero and plotting recurrent event times in the reset rhythm against control event times recurring at the same period, a square lattice of data points can be obtained (Fig 2a). Superimposing many experiments, in which the stimulus struck at all phases of the cycle, one obtains a square lattice of rephasing curves (Fig 2b). The plot is periodic along both time axes. Each unit cell of this 'time crystal' contains as many data points as there were experiments, typically arranged along a smooth rephasing curve that scans some integer number (including 0 as a possibility as in Fig 2b) of cycles vertically as it passes one cycle horizontally. This smoothness is the first fact. It eliminates relaxation-oscillator models, for which an abrupt jump in the rephasing curve is expected at every stimulus duration. (The "breakpoint" or "point of no return"³³ is often depicted in "response curves"—phase shift against original phase—by a data-less vertical dashed line spanning one cycle. This indicates the phase at which the predominant direction of short-term transients in the upset rhythm changes from delays to advances. This typically occurs where the eventual steady phase shift is close to a half cycle. There is no such jump in the rephasing curves.)

The second crucial fact is that every species shows type 1 rephasing in response to sufficiently faint stimuli. This is because a faintly reset rhythm is almost identical to its control, so plotting one against the other gives data points near the rising diagonal in the time crystal. Thirdly, curves with broad regions of negative slope and mean slope 0 are not uncommon and might even occur in all species, given a sufficiently potent stimulus. This eliminates 'simple clock' cycles in all species showing type 0 rephasing.

The fourth crucial fact emerges when the 'time crystal' is extended into three dimensions along a stimulus duration axis. The rephasing curves extend into wavy surfaces, but not separate surfaces as expected of a simple clock mechanism. One finds instead a single corkscrew-shaped surface winding around a vertical symmetry axis (Fig 3). At this isolated singular phase and duration of stimulus, the repeated surfaces connect together by tilting vertically, so that new phase is ambiguous. Following this stimulus, circadian rhythmicity is abolished or only recovers with random phase after an unpredictable lag period (Fig 4). The rephasing curves for stimuli exceeding this critical duration have mean slope 0, those for briefer stimuli have mean slope 1. This is the picture as it emerges in the only two species for which measurements have been carried out in sufficient detail, that is *Drosophila*^{22, 27, 39} and the succulent plant *Kalanchoe*^{36, 37}. Fragmentary evidence from a diversity of other circadian systems, perturbed by diverse rephasing stimuli, seems to fit the same pattern^{38, 39}. This is the pattern expected for limit-cycle mechanisms⁶⁰.

The existence of a singularity reveals states not on the 'clock's' cycle, and establishes the importance of some second and uncontrolled experimental variable, complementary to the 'phase' or 'subjective circadian time' which has apparently sufficed up to now for description of experiments and inference from their results. Perhaps some of

Fig 3 The curved surface depicts new phase (from 0 to 24 vertically) against old phase (from 0 at the rear to 24 at the front) and subjective stimulus intensity (from zero to the right) for the circadian eclosion rhythm of *Drosophila*, as calculated from the simplest oscillator model²⁷. Phase is recorded as h from eclosion peaks (extrapolated back in steps of 24 h) to stimulus time. The 1,327 data points represent eclosion peak centroids of clearly rhythmic populations ($R < 50$)⁶⁶, in experiments covering four cycles of old and new phase, all reduced to this one unit cell. Subjective stimulus intensity is exposure energy divided by an exponential dark-adaptation factor. Note that exposure during an eclosion peak (phase 0, the front and back edges) does not affect subsequent eclosion timing, and exposure midway between peaks at a critical intensity results in ambiguous phase (the vertical pole around which the surface and data climb). The data and surface in this unit cell would fit smoothly on to replicas above, below, in front, and behind.

those inferences could now be re-examined. A similar dilemma seems to be arising through Kauffman and Wille's application of similar experiments^{50, 61} to the cell cycle—the familiar 'simple clock'³⁸ and 'mitogen relaxation oscillator' interpretations³¹ of cellular control over mitosis provide no interpretation for a singularity or for type 0 rephasing.

Limit cycle excluded experimentally

In the singularity we are confronted with a first 'unclock-like' aspect of circadian chronometry. A second emerges from the attempt to pursue the idea of a quickly recovering limit-cycle mechanism through the entrainment of circadian rhythms by stimuli repeated at 24-h intervals.

Perkel *et al.*³⁵ carried out an elegant theoretical and empirical analysis of entrainment for pacemaker neurones exposed to regular synaptic input at millisecond intervals. This analysis is built on the assumption that the oscillator pops instantaneously from one phase to another of its cycle. The same assumption led to the same equations in Ottesen⁶², Pavlidis³³, and Pittendrigh's⁶³ analysis of circadian rhythmicity (hence the acronym 'POPP' model). The success of the POPP model for circadian rhythms in its only experimental tests (using *Drosophila*⁶³, *Kalanchoe*

flowers⁶⁴ and sparrows⁶⁵) makes it worthwhile to test directly its underlying assumption that the circadian mechanism, being a simple clock, relaxation oscillator, or quickly-recovering limit-cycle mechanism, essentially pops from one point to another on its cycle when reset.

Checking this assumption would be unnecessary if the circadian oscillator were a simple clock or relaxation oscillator, which have no accessible states other than the usual cycle. The fact that rephasing curves are smooth and change abruptly at a critical stimulus duration from mean slope 1 to mean slope 0 both excludes those two models and shows that the POPP rule requires amendment for application to limit-cycle mechanisms: for if all stimuli leave the oscillator very nearly on its limit cycle, then a long stimulus, evoking type 0 resetting, can be viewed as an uninterrupted sequence of shorter stimuli, but under POPP rules, any sequence of type 1 stimuli still gives type 1 resetting. Perhaps the POPP rule must be restricted to 'strong' stimuli or to stimuli that are 'not too close together'. In measuring how strong is 'strong' or how close is 'too close', we determine how quickly the circadian oscillator recovers to its limit cycle after a disturbance. Such an experimental test of the POPP rule in *Kalanchoe* discovered no systematic deviation from its predictions for stimuli at least 2 h apart⁶⁴, though the data fit as well to a limit-cycle model with recovery time in the order of a day^{56,57}.

But in *Drosophila*, no evidence of recovery was found. In 600 experiments, a once-reset rhythm was subjected to a strong second stimulus at various times to measure the rephasing curve of a previously reset oscillator: how quickly does it return to normal, leaving only a phase shift equal to that observed in the overt behavioural rhythm? The normal phase-dependence of the phase response was found to be attenuated in proportion to the nearness of the first stimulus to the singularity, and there was no sign of return to normal during the 48 h examined by a second pulse, for such stimuli, any interval is 'too close'. No such attenuation was conspicuous following stimuli far from the singularity, for such stimuli no interval is 'too close'^{56,67}.

So the fly's clock does not resemble a quickly recovering limit cycle mechanism, either. What it does resemble is a simple harmonic oscillator—for example a pendulum—in which disruptive stimuli result in permanent, co-ordinated shifts of both phase and amplitude without effect on frequency. In fact, a mathematical metaphor of this sort fits the data from over 1,000 diverse one-pulse and two-pulse rephasing experiments on the circadian rhythm of eclosion of *Drosophila* to within almost the reproducibility of measurements (ref. 66 and A.T.W. in preparation). The theory of isochrons and phase resetting which originally predicted the singular stimulus^{50,60} cannot be rigorously applied to such mechanisms.

Organism as a clockshop

What can such a grotesque coincidence possibly signify? The thought that most tantalises me is that the individual fly's behavioural rhythm may be determined by superposition of at least two independent circadian oscillations, each possibly arising from a simple clock, relaxation oscillator, or limit cycle mechanism. (Care was taken⁶⁸ to exclude the possibility^{56,57,64,66,70} that attenuated rhythmicity arose as an artefact of phase incoherence among individually coherent pupae of the sampled populations.)

From such indications as the overt desynchronisation of circadian rhythms among the organs and cells of higher plants⁶, the splitting of activity rhythms in flies⁷¹, bees⁸, birds⁷³, rodents⁷⁴ and primates⁷⁵, some workers have speculated that the organisms more resemble a clockshop

than a clock^{70,73-80}. Populations of weakly interacting idealised oscillators have been shown to exhibit mutual synchronisation, splitting, and more complex quasi-rhythmic idiosyncrasies resembling those observed in large multicellular organisms^{44,81}. By an adjustment of the phase relation between their mutual influence and sensitivity rhythms, they can just as easily repel each other to remain uniformly distributed around the cycle⁴⁴. Thus overt arrhythmicity in some species is not incompatible with the notion that cellular metabolism is typically organised in 24-h patterns.

Since direct control of circadian rhythms by sensitive extra-retinal photoreception is quite common, even among vertebrates²⁻⁶, there might be little need even for weak interactions among independent cellular oscillators, all cells being synchronised in parallel directly by the external light/dark cycle. Only when completely coherent does such a population exhibit the resetting characteristics typical of the individual oscillator mechanism. This may be the situation in entrainment experiments, and the deepest reason for success of the POPP model's predictions for entrainment, despite the failure of its prediction for general two-pulse interaction.

Even though a simple clock, for example, cannot show type 0 rephasing or a singularity, the summed outputs of a population of simple clocks can if its independent members are not quite synchronous when the stimulus starts. A properly timed stimulus of the right duration greatly increases the incoherence of such a population, resulting in attenuation of the collective rhythm and correspondingly attenuated rephasing curves. Both persist as though the 'amplitude', 'intensity' or 'vigour' of circadian oscillation had been reset without affecting its period, because without interactions and without much dispersion of cellular periods, the variance of cellular phases would not change. This variance of cellular phases may be the 'second and uncontrolled experimental variable' suggested above.

These matters are elaborated in more detail (A.T.W. in preparation) elsewhere: the point I wish to make for present purposes is that the unclocklike peculiarities encountered in the most thoroughly studied circadian rhythms might be accounted for in three different ways.

(1) Without invoking a multiplicity of independent oscillators, by finding a plausible mechanism with amplitude as labile as phase, and frequency nearly independent of amplitude. Predator-prey kinetics on a chemical level has this character⁸². Goodwin^{15,83} proposed a mechanism based on control of nuclear DNA-dependent RNA synthesis which could oscillate with a period of many hours in the required orbitally stable way.

(2) By supposing that whole-organism behaviour is governed by the superposition of two identical and independent smooth limit-cycle oscillations of 24-h period, perhaps one on each side of the brain^{71,72}. When their phases differ greatly, for example after both have independently recovered to random phases from near the singularity, the 24-h component of their combined outputs would be quite weak. This idea could be tested by one-sided surgical "clockectomy".

(3) By taking seriously the evidence noted above that circadian rhythmicity is an autonomous cellular process. If the cells are assumed not to interact much (as in a clockshop), then whether they are simple clocks, relaxation oscillators, or limit cycle mechanisms, the qualitative peculiarities of rephasing behaviour follow, thus harmonising phylogenetically widespread rephasing behaviour with the apparent diversity of evolutionary origins and physiological mechanisms of circadian rhythmicity.

On this alternative, the damping rate of free-running rhythms measures the range of individual cell periods and the 'clockshop' conjecture is implausible to the extent that this range is implausibly small. Persistence of rhythmicity in

Fig 4 The eclosion rhythm of 8 populations of *Drosophila* is recorded hourly through days 4–8 after stimulus time. Each mark in the histogram represents 1 fly. Populations 1–4 received about 5,000 erg cm⁻² of blue light near subjective midnight. Their rhythmicity is attenuated relative to populations exposed at any other combination of intensity and phase, in all cases, for example histograms 5–8, the normal rhythm is merely phase-shifted (in Figs 2 and 3, peaks like the 15 shown here are each represented by a single dot).

Drosophila for at least 1 d without indication of damping^{28, 70} suggests a dispersion of periods smaller than 2%. In *Gonyaulax* cell suspensions, rhythmicity of cell division persists unattenuated for at least 10 days⁴¹. Assuming no mutually synchronising interactions, this also suggests that cell clocks differ in period by less than about 2%. Chemical interactions were tested for by mixing differently phased cell suspensions without revealing any tendency to synchronisation^{45–87}. The corresponding test in multicellular animals or plants would be parabiosis of individuals reared on different light cycles, or parabiosis of a rhythmic individual with one rendered arrhythmic by the singular stimulus. Discovery of strong synchronising interactions would eliminate the 'clockshop' conjecture⁸⁸ (Of course electrical interactions among nerve cells would escape detection by these means).

Finally, this model predicts that an organism in the low-amplitude condition should exhibit a conspicuous scattering of cell phases. No such dispersion of cellular clocks states is predicted under the orbitally stable oscillator model (1). Since some cells exhibit circadian rhythms of nuclear volume, chloroplast shapes and so on⁶, this might afford a critical test of the 'clockshop' conjecture.

Either way, there remains the Darwinian question: given labile amplitude, how does it fit into the organism's life style? Has it a selective advantage or is it an 'accidental' selectively neutral by-product of something more important? My guess is that the clockshop hypothesis is correct, and that 'amplitude' lability is a laboratory artefact, the cellular incoherence necessary for its appearance being rare under field conditions of entrainment to natural photoperiods. The possibility should, however, be investigated that this 'unclocklike' feature of circadian organisation is hinting to us of some adaptive role other than the 'time' and 'phase'-oriented purposes considered up to now.

Mesozoic and Cainozoic opening of the Labrador Sea, the North Atlantic and the Bay of Biscay

Willem J. M. van der Linden

Atlantic Geoscience Centre, Geological Survey of Canada, Bedford Institute of Oceanography, Dartmouth, Nova Scotia, Canada

A reinterpretation of magnetic anomaly and basement trends suggests that the Labrador Sea opened in two stages. During a first phase, most likely in the late Jurassic–early Cretaceous, the opening was coupled, by way of a triple junction off Spain, to spreading in the central Atlantic and Bay of Biscay. A second phase of seafloor spreading in the Labrador Sea occurred between 60 and 47 Myr ago and was connected through a triple junction south of Greenland to spreading in the northern and central Atlantic.

THE Labrador Sea is thought to have formed as the result of the rifting apart of Labrador and Greenland and the formation and spreading of the sea floor in between^{1–11}. The correlation of magnetic and basement trends presented here differs from that of previous workers^{4,7,11,12} and points to an alternative geometry and spreading history for the Labrador Sea and the North Atlantic Ocean.

Magnetic trends

The residual magnetic field over the north-western Atlantic Ocean and the Labrador Sea (Fig. 1) is derived from maps in refs 4, 11, 12 and 13. Although there are inconsistencies, the overall trends and characteristics of the anomaly sequences match very well.

Over the Labrador Shelf, Precambrian rocks, covered by a wedge of seaward-thickening sediments, produce a pattern of chaotic high frequency anomalies. The zone beyond the shelf edge, which is 170 km wide and underlies the Continental Slope and Rise, is interpreted as foundered continental crust¹³. The magnetic field over this zone is characterised by small amplitude, large wavelength anomalies that run parallel to the margin. The approximate seaward limit of this zone (Fig. 1) is interpreted as the true boundary between continent and ocean.

In the Labrador deep sea, there are two sequences of oceanic anomalies with a regular and parallel pattern. Sequence I comprises all anomalies that run NW–SE, in the northern and in the southern parts of Fig. 1, although they are partially separated by a central zone of attenuated anomalies. The attenuated anomalies outline a basement high (the Cartwright Arch), which is the offshore extension of the Grenville Province¹³. Sequence II, labelled 19–24 in Fig. 1, runs almost due north from the Charlie Gibbs Fracture Zone up to about 56°30'N. There it bends westwards through approximately 80°,

and continues along this trend for about 200 km. Here the sequence changes direction again and at the same time the anomalies converge, they finally wedge out at approximately 57°N 50°30'W.

The termination of sequence II provides the key to the new correlation. The pattern is more clearly illustrated in Fig. 3a of Vogt and Avery¹¹, where the anomalies are presented with a contour interval of 50 gamma. The new correlation differs from earlier correlations^{4,7,11,12}, which, despite the pinching out near 57°N, continue sequence II into the northern part of sequence I.

The age of sequence II has been defined accurately using the time scale of Heirtzler *et al.*¹⁴. A match was obtained with anomaly sequence 19–24 which indicates that spreading occurred 47 to 60 Myr ago^{4,12}. The age of sequence I has not been accurately determined and various spreading periods have been postulated: 65–80 Myr (ref. 3), 60–80 or 82 Myr (refs 4 and 12), 60–76 Myr (ref. 5) and 38–52 Myr (ref. 7). The estimates (with one exception⁷) focus on a period, immediately prior to the generation of sequence II, in the late Cretaceous and early Tertiary. Many authors have considered an even earlier (perhaps epicontinental, perhaps rifted) Labrador Sea, in existence before the generation of anomaly sequence I (refs 2, 4, 5, 10, 11, 15, 16).

Basement trends

The basement morphology of the Labrador Sea region south-west of Greenland parallels the magnetic anomalies. In Fig. 1, I have indicated the culminations of basement as defined in refs 1, 4, 5, 9, 12, 13 and 15. The authors interpreted these basement highs as expressions of fossil mid-ocean ridges or former centres of seafloor spreading. Laughton considered the east–west trending basement structures at about 57°N to be continuous with north-westerly trending basement structures in the northern Labrador Sea. Vogt and Avery¹¹ accept this interpretation and propose the name Ran Ridge for this fossil mid-ocean ridge.

The correlation of basement trends is similar to that of the magnetic trends. Thus, the NW–SE trend of the mid-Labrador basement highs, parallel to magnetic sequence I, is probably continuous from the northern Labrador Sea to the Charlie Gibbs Fracture Zone. Also the east–west trending ridge, parallel to magnetic anomaly sequence II, probably terminates at about 51°W. In Fig. 1, the magnetic lineations associated with the

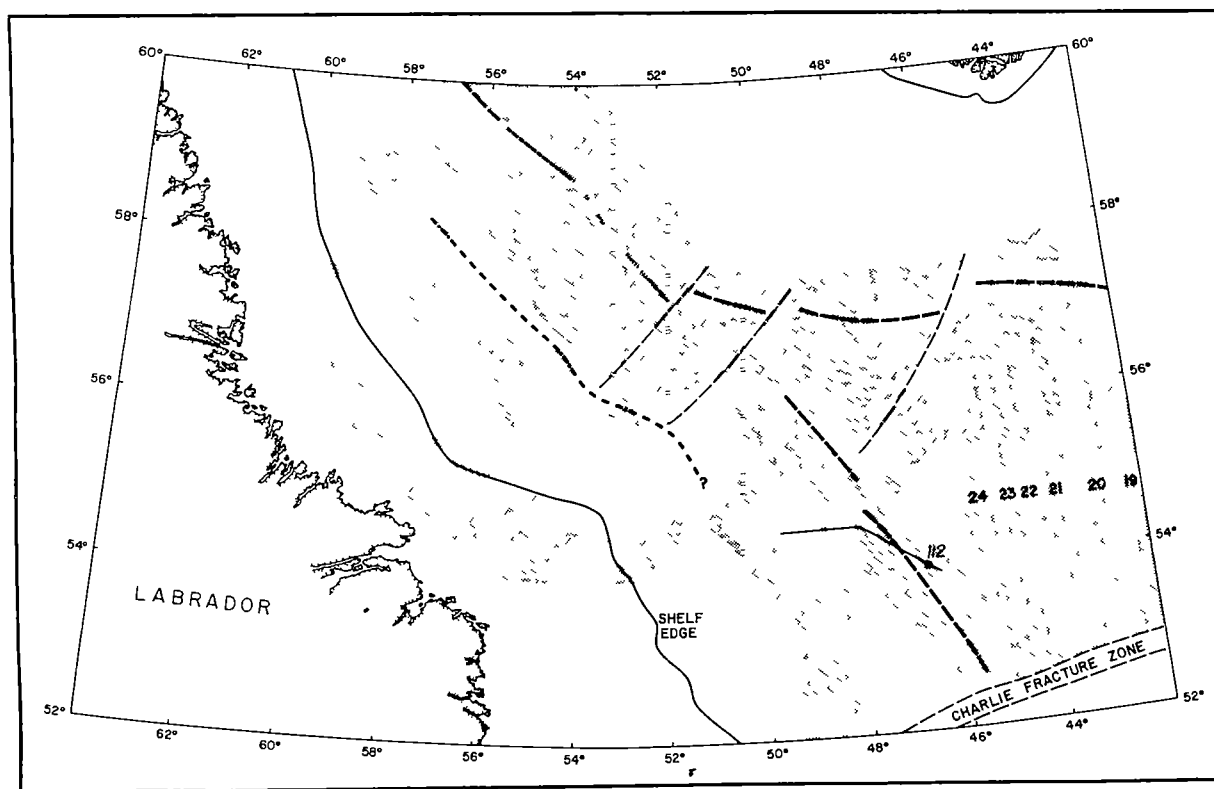

Fig 1 Observed (— — —) and inferred (---) positions of basement highs superimposed on the distribution of positive (shaded) and negative magnetic anomalies in the Labrador Sea (after refs 4, 5, 9, 11 and 13) — — — —, The inferred continental-ocean boundary. Correlation of anomalies with the time scale of Heirtzler *et al*¹⁴ is shown for the sequence 19–24. DSDP site 112 is marked, as well as the position of a CSS Hudson reflection profile (Fig 5) through the site

eastern half of the NE-SW spreading are only partly shown. Information from south of Greenland is too sparse and has not been included on the map. Farther north, however, aeromagnetic surveys^{7, 17} indicate a mirror image of the western Labrador magnetic anomalies on the Greenland side (Fig 2). A belt of relatively high frequency anomalies can be distinguished on both sides of a central low amplitude sequence. The centre of spreading (Fig 2) coincides with the position of the fossil mid-ocean ridge (Fig 1).

Labrador Sea and North Atlantic

Figure 3 combines the information for the Labrador Sea with the magnetic anomaly pattern and major structures of the North Atlantic Ocean. Sequence II (anomalies 19–24) is very well defined and can be easily correlated, particularly north of the Charlie Gibbs Fracture Zone (CGFZ)^{9, 11}, where it is undisturbed by fracture zones. In contrast, the correlation of anomalies and comparison with the magnetic time scale are often ambiguous for sequence 5–18 (9–46 Myr BP), especially south of the CGFZ. The various isochrons, both north and south of the CGFZ, each identified with their age in millions of years, were taken from Pitman and Talwani¹⁸. The anomaly pattern in the Bay of Biscay and the area immediately to the west of the Bay is taken from Williams¹⁹. Vogt and Avery¹¹ indicate two basement ridges, West Thulean Rise and East Thulean Rise, about equidistant on either side of the Mid-

Atlantic Ridge, south of the CGFZ. These ridges are significant in the reconstruction of the North Atlantic, as will be shown. In the eastern Atlantic, north of the CGFZ, the magnetic anomalies run in a south-easterly direction^{4, 11, 12} (oblique to the 19–24 sequence to the west and parallel to the East Thulean Rise). Across the CGFZ, these anomalies do not match closely the anomalies shown by Williams¹⁹ west of the Bay of Biscay. Certainly the 81-Myr isochron through this area¹⁸ is doubtful.

Fig 2 Four aeromagnetic profiles across the northern Labrador Sea (after Hood and Bower⁷) with estimated position of centre of symmetry (---) and inferred continent-ocean boundary (---). Amplitude scale in gamma.

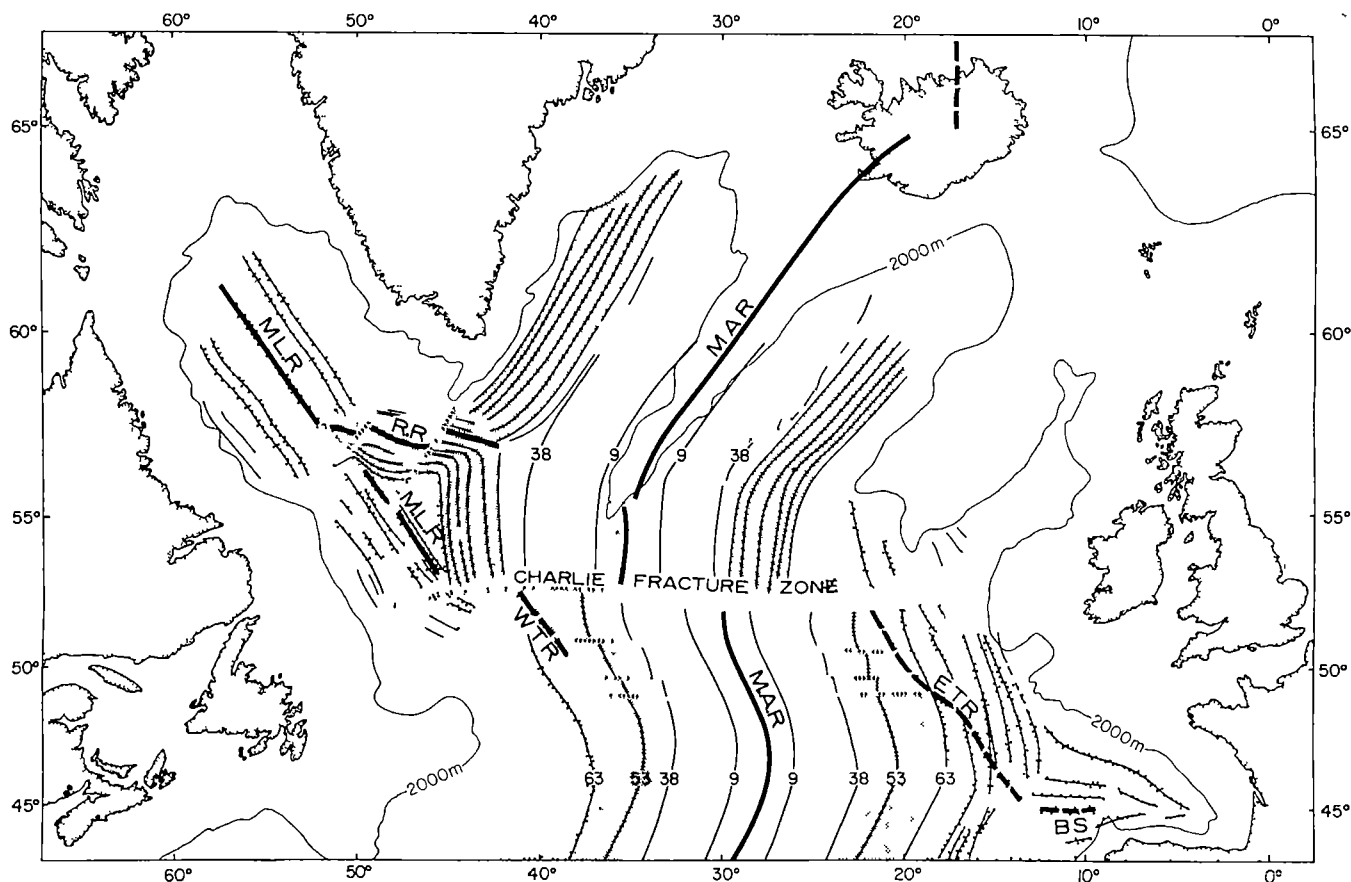

Fig. 3 Position of spreading centres (— — —), major faults (— — —), magnetic anomalies and isochrons (labelled) in the North Atlantic Ocean, modified after refs 9, 11, 18 and 19. Magnetic anomaly sequence 19–24 (47–60 Myr BP) is densely shaded. Seafloor area generated during the Mesozoic is approximated with open shading. Fig. 4 The North Atlantic Ocean at the end of the Mesozoic. Seafloor area generated during the Mesozoic (phase I) is approximated with shading. The reconstruction is produced by removing the seafloor generated in the past 60 Myr (phase II and younger) and closing the gap. Note that the transform fault north of the Charlie Gibbs Fracture Zone approximates the position of the Ran Ridge. MAR, Mid-Atlantic Ridge, BS, Biscay Seamounts, GF, Grenville Front.

and is thus not included in Fig 3 The 81-Myr isochron off the Grand Banks of Newfoundland is also omitted, for similar reasons

I would like to retain the old name Mid-Labrador Ridge for the spreading centre, about mid-way between Labrador and Greenland, and to restrict the name Ran Ridge¹¹ to the east-west trending ridge, centred on anomaly 19

The following reconstruction is proposed for the Labrador Sea Phase I—the Labrador Sea opens between Greenland and Labrador with spreading centred on the Mid-Labrador Ridge Phase II (60–47 Myr BP)—seafloor spreading is centred on the Ran Ridge and coupled through a triple junction to spreading on the Mid-Atlantic Ridge

Fig 5 Line tracing of 1,000 inch³ air gun reflection profile and associated magnetic anomalies in the Labrador Sea (CSS Hudson, cruise 72–025). Vertical scale for the reflection profile is in seconds two-way travel time. Vertical exaggeration 33:1 at water velocity. Vertical scale for the magnetic profile is in gamma. NWAMOC, North West Atlantic Mid-Ocean Channel. DSDP 112, Deep Sea Drilling Project site 112. For the position of the line see Fig 1. Note the coincidence of the positions of negative magnetic anomalies and positive basement relief.

It is suggested that the spreading activity in the Labrador Sea during phase I was coupled to spreading in the Bay of Biscay^{15,20}. About 60 Myr ago the East and West Thulean Rises were one ridge system, as can be demonstrated by reversing the spreading in the Atlantic since that time (Fig 4). Williams¹⁹ suggested a triple junction that tied the largely north-south directed opening of the Bay of Biscay to east-west directed seafloor spreading in the eastern Atlantic Ocean during the Mesozoic. Thus, spreading was centred on the Mid-Labrador-Thulean ridge system, Biscay Seamounts, and Mid-Atlantic Ridge. The reconstruction (Fig 4) suggests that during phase I the Ran Ridge was a transform fault that trailed the Grenville Front¹³.

Age of spreading

The age of seafloor spreading during phase I is not firmly established but it certainly predates spreading during phase II. The shift of 25° from phase I (NE–SW spreading) to phase II (east–west spreading) (Fig 1) constitutes a major change in the orientation of plates that most likely represents a hiatus in the spreading of the Labrador Sea.

Support for a late Cretaceous–early Tertiary age for phase I comes from Deep Sea Drilling Project (DSDP) site 112 (ref 21). Basement samples cored at the site consisted of weathered basalt that could not be dated. A minimum age of 65 Myr was inferred for the basement from the age of the oldest sediments cored above the basalt. A seismic profile through the site taken by CSS Hudson (Fig 5) indicates that this inference is

misleading. Eighty kilometres to the north-west the thickness of the sediments above the basement is twice the thickness found at site 112, which suggests a minimum age of the basement of 130 Myr. If a contemporaneous opening of the Labrador Sea and the Bay of Biscay is accepted then the identification of magnetic anomalies 31–32 in the Bay¹⁹ supports a late Cretaceous age for episode I. An earlier interpretation of the same anomaly pattern²², however, suggests a late Cretaceous age for the Bay of Biscay.

There are other arguments in support of an earlier, possibly Jurassic phase of opening of both the Labrador Sea and the Bay of Biscay. On the basis of geological and geophysical evidence from both Spain and France (stable Europe), the Bay of Biscay is considered to have been formed between the Triassic and late Cretaceous²³. Results from DSDP sites 118 and 119 in the Bay of Biscay suggested to Laughton¹⁷ that the oldest sediments below the deepest dated horizon in the Bay (Palaeocene) may be as old as early Cretaceous. Palaeomagnetic results suggest an opening of the Bay of Biscay some time between the Triassic and late Cretaceous²⁴. Larson and Pitman²⁵ elaborated on the interpretation of Williams and McKenzie²² and suggested that the Biscay anomalies may be part of the Keathley sequence and thus that the Bay opened between 150 and 110 Myr BP. Correlation of the Labrador Sea and Keathley anomalies is indeed at least as good (or as bad) as the correlations between the Labrador anomalies and the Cretaceous magnetic timescale. The position of the Keathley anomalies in the central Atlantic^{18,26} would then identify the position of the third or southern Middle Mesozoic spreading arm, radiating from the Williams¹⁹ triple junction.

As mentioned, several authors favour partial opening of the Labrador Sea during Jurassic time, although no one has suggested a Jurassic age for the northern Labrador magnetic anomalies. McMillan^{10,16} argued for a Mesozoic initiation of the Labrador Sea to explain the occurrence of Jurassic carbonates collected from the Labrador continental slope.

Further support for late Jurassic–early Cretaceous rifting of the Labrador Sea comes from a series of dikes that run parallel to the coast in south-west Greenland²⁷, these have been dated as late Jurassic (138 Myr). Dike intrusion may, however, have predated actual spreading by several million years.

From the available evidence, I am inclined to accept a late Jurassic age as the most plausible for the opening of the Labrador Sea and the Bay of Biscay. A more definitive answer to the problem will have to come from more closely spaced magnetic surveys and from dated oceanic basalts in crucial areas.

I propose that (1) the Labrador Sea was formed during two phases of seafloor spreading, one in the late Jurassic–early Cretaceous and one in the early Tertiary, and (2) the Labrador Sea opening in the Mesozoic was coupled with seafloor spreading in the North Atlantic Ocean and the Bay of Biscay.

As an alternative to earlier interpretations^{4,5,12}, this model simplifies the geometry of the Atlantic evolution. A Jurassic age, suggested for the early phase of opening, is in better agreement with geological observations on the Labrador Sea margin and the Bay of Biscay. It also suggests that Mesozoic seafloor spreading in the Atlantic Ocean was not restricted to the area south of the Azores–Gibraltar Fracture Zone¹⁸.

There are several areas which have to be examined if the model is to be refined—notably, between the East Thulean Rise and Europe, between the West Thulean Rise and the Grand Banks, and between Greenland and the Ran Ridge. These areas are all near continental margins and are probably structurally complex.

Drs L. H. King and R. K. H. Falconer reviewed the manuscript.

Nucleic acid-mutagen interactions: crystal structure of adenylyl-3',5'-uridine plus 9-aminoacridine

Nadrian C. Seeman, Roberta O. Day* & Alexander Rich

Department of Biology, Massachusetts Institute of Technology, Cambridge, Massachusetts 02139

Adenylyl-3',5'-uridine and 9-aminoacridine cocrystallise in a heavily hydrated monoclinic lattice. The adenine residues are hydrogen bonded with uracil residues and the base pairs are stacked parallel to each other in the crystal with 9-aminoacridine sandwiched directly between them.

In 1961 Lerman¹ suggested that planar aromatic aminoacridine molecules can be inserted between the base pairs in DNA. This mode of molecular interaction has been widely accepted and many interactions between nucleic acids and planar molecules have been explained in terms of an intercalation model. A number of varied molecules including carcinogens and mutagens have a mode of action which is believed to be intimately associated with the intercalation mechanism. In spite of a great deal of chemical and biological work, however, the detailed structure of intercalation complexes has not been determined. In part, this reflects the fact that it is difficult to obtain structural information at atomic resolution from X-ray diffraction studies of polymeric nucleic acids combined with intercalating agents. In view of the large number of important biological phenomena associated with intercalation, it is desirable to understand the detailed interactions of planar intercalating molecules with hydrogen bonded base pairs. Here we report the crystal structure of complex containing the dinucleoside phosphate adenylyl-3',5'-uridine (ApU) and the mutagen 9-aminoacridine. In the heavily hydrated crystal lattice the adenine and the uracil residues are hydrogen bonded while the 9-aminoacridine molecules are sandwiched between the base pairs and stacked parallel to them.

Experimental details and solution of structure

A solution of 5 mg of ApU (Sigma) in 0.25 ml of a 200 mM sodium cacodylate buffer at pH 6.6 was prepared. A 4.16 mg sample of 9-aminoacridine hydrochloride was dissolved in this solution, followed by the addition of 0.1 ml of isopropanol. The vial was sealed, and crystals suitable for diffraction analysis appeared within a week. These crystals were unstable in the

absence of the mother liquor and had to be mounted in a sealed capillary. The lattice constants were determined and intensity data were collected on a Syntex PI diffractometer. The crystal data are $a=13.261 \text{ \AA}$, $b=26.677 \text{ \AA}$, $c=6.922 \text{ \AA}$, $\beta=95.08^\circ$, space group $P2_1$. Intensity data were collected for 3,553 Friedel pairs using nickel filtered $\text{Cu K}\alpha$ radiation. 2,874 reflections were observed on the basis of a 2σ significance criterion. Lorentz and polarisation corrections were applied to the intensity data, but no absorption correction has been calculated.

The standard method for solving crystal structures of dinucleoside phosphates has been to locate the phosphorus atom by means of resolution difference techniques²⁻⁴. Many attempts to apply this technique to this structure were unsuccessful because the phosphorus-phosphorus vector was hidden under a large peak on the Harker section. We were therefore forced to locate the phosphorus atom by the use of the anomalous dispersion data available from the phosphorus which has 0.43 anomalous electrons. Once the phosphorus was located, the rest of the structure was readily obtained in a series of seven Fourier cycles and the water structure was determined in a series of difference Fourier calculations. The crystal structure has been refined using least squares and anisotropic thermal parameters to a conventional R factor of 7%. The disorder in the water structure has made it impossible to locate hydrogen atoms.

Description of the structure

The molecular structure and numbering for ApU and 9-aminoacridine are shown in Fig. 1. Figure 2 shows a view of the complex perpendicular to the plane of the adenine-uracil base pair and the 9-aminoacridine molecule. In Fig. 2 the monoclinic b axis is in a horizontal orientation and the twofold screw relationship between successive molecules is clearly shown in the diagram. The thickness of the unit cell perpendicular to the plane in Fig. 2 is 6.9 \AA which is twice the thickness of the planar aromatic rings. It can be seen that the adenine-uracil residues are hydrogen bonded in pairs using the nitrogen 6 of adenine bonding to oxygen 4 of uracil (hydrogen bond length $=2.99 \text{ \AA}$) and nitrogen 3 of uracil bonding to nitrogen 7 of adenine (2.84 \AA). This hydrogen bonding arrangement, first observed by Hoogsteen⁵, has been seen in a large

*Also at Department of Chemistry, University of Nebraska, Lincoln, Nebraska 68508

number of purine-pyrimidine complexes⁶ The hydrogen bonded base pair is surrounded on both sides by 9-aminoacridine molecules as shown in Figs 2-4 In addition to this, the adenine residues are hydrogen bonded to the ribose hydroxyl groups of an adjoining uridine where the interactions are between the N6 amino group of adenine and O3' of the ribose (2.95 Å) and between N1 of adenine and O2' of the same uridine ribose (2.77 Å) Although the hydrogen bonding to uracil involving the adenine imidazole N7 nitrogen has been seen in many complexes, the hydrogen bonding between adenine and ribose in this specific manner has not been seen previously

The projection in Fig 2 shows an unusual circular cylindrical channel, the walls of which are composed of four different molecules of ApU and three molecules of 9-aminoacridine The entire structure is built out of clusters of these cylindrical complexes, one complete unit of which is shown in Fig 2 The interior of the cylinder is heavily hydrated containing 15 water molecules which are disordered among 21 loci in the asymmetric unit Since these hydrated channels go through the entire crystal, it is likely that this gives rise to the instability of the crystal on drying

Figure 3 shows a view of one segment of the wall of the cylindrical channel viewed perpendicular to the direction shown in Fig 2 Here the insertion of the planar 9-aminoacridine molecules is shown between the adenine-uracil hydrogen bonded pairs The adenine-uracil pairs are nearly coplanar, but have a slight propeller twist of 4° between them

Fig. 1 The chemical formulae and molecular numbering system for adenylyl-3',5'-uridine and 9-aminoacridine

Nucleoside conformations are unusual

The perturbation of the dinucleoside phosphate structure by the mutagen results in some unusual features for the nucleosides The adenosine ribose has a C2' endo conformation with a glycosidic torsion angle of 77° which is in a region between the syn and anti conformations^{7,8} The glycosidic torsion angle is not unusual for nucleosides which have a C2' endo ribose, however, this is the first time that a C2' endo conformation has been seen in a dinucleoside ribophosphate The ribose of the uridine nucleoside is in the more familiar C3' endo conformation, however, the glycosidic torsion angle is again

Fig. 2 A view of the structure perpendicular to the planes of the bases and 9-aminoacridine The 9-aminoacridine does not have darkened bonds The dashed lines indicate the hydrogen bonding interactions of adenine The *b* axis is horizontal, and the cylindrical water channel is seen here

rather unusual having a value of 71° which has not been reported previously for the 3' endo sugars As can be seen in Fig 3, the bases are approximately parallel to the ribose O1'-C4' bonds rather than O1'-C1' as is usually the case^{8,9} It is interesting that the puckering of the adenosine ribose ring and the values of both glycosidic torsion angles are characteristic features of deoxyribonucleotides rather than ribonucleotides¹⁰

The backbone connecting the two nucleosides is in a helix-reversing A1 conformation⁹ which was first seen in the crystal structure of UpA² All the bond angles and distances in the dinucleoside phosphate are in the normal range, the only unusual features of the structure associated with the perturbation caused by the acridine are the unusual glycosidic torsion angles and the conformation of the adenosine ribose ring In contrast to this the torsion angles of the backbone are comparable with those which have been observed in all previous dinucleoside phosphate structures^{2-4,11} It is interesting to ask what would happen if one inserted the adenosine and uridine nucleosides observed here into a double helical structure such as those found for the sodium salts of ApU³ and GpC⁴ The result would be a structure with an increased distance between the adjacent bases along the chain The normal 3.4 Å stacking distance would be approximately doubled, allowing the acridine to be intercalated between the base pair

A view of the hydrophobic intercalated column containing the acridines and the base pair is shown in Fig 4 where we are viewing the column at an angle which allows us to visualise both the base pair and the acridine atoms The unusual glycosidic torsion angles can be seen in this projection as well as in the projection shown in Fig 3

Fig 3 A view of the intercalative structure perpendicular to the view in Fig 2. The bases and 9-aminoacridine are viewed end on. The acridine molecules have darkened bonds.

Stacking interactions

Water molecules are excluded from the hydrophobic column shown in Figs 3 and 4, and this undoubtedly contributes to its stability. The stacking interactions are very great in this complex and these no doubt provide the driving force for forming the complex. The water excluded from these areas is found in the elongated channels. The detailed nature of the water structure will be described elsewhere.

Another feature of the present structure is the fact that electrostatic interactions probably play only a small role in stabilising the structure. The acridine molecule is charged and, as shown by Talacki *et al.*¹², part of the positive formal charge resides on the amino group and part is on N10. These atoms are both more than 6 Å away from the nearest phosphorous atom. Because of this considerable distance electrostatic interactions are likely to be far less important in stabilising the structure than the considerable stacking interactions. It is interesting that the acridine C9-N9 bond is antiparallel to and almost overlapping the adenine C8-N7 bond. This and other overlaps seen in Fig 2 suggest that the fine details of the stacking may be stabilised by small local electrostatic interactions.

The detailed nature of the interaction of the 9-aminoacridine with the base pair is of interest. Figure 2 shows that each of the two outer six-membered rings of the acridine is largely overlaid by a purine or a pyrimidine. The centre ring is largely found in the region occupied by the hydrogen bonding interactions. The relationship of the stacking interactions seen with this hydrogen bonding to the interactions which might be found in a double helix involving the normal Watson-Crick hydrogen bonding is not entirely clear. One possibility, however, is that the interaction of the 9-aminoacridine with either the uracil or the adenine might be preserved in a double helix. If the uracil-acridine interaction were conserved with a normal Watson-Crick base pair, heavy overlap with the adenine would result. Alternatively, if the overlap with the adenine residue were maintained, there would be no overlap between acridine and the uracil. However, in this latter position the 9-amino group of the cationic mutagen would be in a position to form strong hydrogen bonds with the anionic phosphate group. It is interesting that two different binding modes have been described for intercalating agents¹³.

Features of this mutagen-dinucleoside phosphate complex might have relevance in other structures. It is known that planar intercalative molecules can combine with transfer RNA¹⁴. There are two hydrogen bonding interactions in yeast phenylalanine tRNA which involve uracil derivatives hydrogen bonding to imidazole N7 of adenine^{15,16}. It is conceivable that the interaction of planar intercalating molecules may interact at these sites in a manner similar to that seen in this structure. Another interesting feature of the present

structure is the unusual hydrogen bonding found between the ribose residue and the adenine ring. This type of interaction might be specific for adenine and it might be associated with some of the constant adenine residues which are found in tRNA where they may hydrogen bond to ribose residues.

This is the first molecular structure analysis carried out at atomic resolution which clearly indicates the mode of intercalation of a mutagen between an adenine-uracil base pair. The structure has some unusual features, some of which are suggestive of the manner in which planar molecules may be intercalated into double helical structures or into other more complex nucleic acid structures such as tRNA or ribosomes. This structure illustrates one stable mode of interaction between a mutagen and a base pair. Aspects of this structure may be of help in providing a detailed understanding of the mode of action of mutagens in biological systems.

Fig 4 A view of the intercalative stacking interaction at an oblique angle. The nature of the vertical hydrophobic column of alternating base pairs and 9-aminoacridine is seen here.

We have had informative discussions with Drs G. J. Quigley, R. D. Rosenstein and J. M. Rosenberg. We thank Dr V. W. Day for assistance in collecting diffraction data. This research was supported by grants from the National Institutes of Health, the US National Science Foundation and the American Cancer Society. N.C.S. and R.O.D. are fellows of the National Institutes of Health. We thank the University of Nebraska Computing Center for the use of their facilities.

Note added in proof: We were recently sent a preprint of a paper by C. C. Tsai, S. C. Jain and H. M. Sobell describing the crystal structure of an ethidium-dinucleoside phosphate complex in which ethidium is intercalated in a fragment of RNA double helix¹⁷. The nucleosides show some of the same perturbations described here. We thank Dr Sobell for providing us with this information.

letters to nature

Jupiter's main magnetic field measured by Pioneer 11

THE first *in situ* studies of the magnetosphere of Jupiter were conducted in November and December, 1973, by the spacecraft Pioneer 10. An analysis of the helium magnetometer data¹ indicated that the planetary magnetic field was well represented by an offset tilted dipole (OTD) at distances less than $10R_J$ (R_J =radius of Jupiter=71,372 km). But the movement (4.0 gauss R_J^{-3}) and tilt (10.6° at $\lambda_{III}=$

Fig 1 Path of Pioneer 11 spacecraft as function of magnetic latitude, θ , and distance, D , near closest approach to Jupiter, which occurred at 0522 GMT December 3, 1974. Numbers on path indicate time (GMT). Location of orbit of satellite Io is indicated.

222°) of this model, identified at D_2 , yielded a field configuration and intensity which were inconsistent with several earlier independently derived estimates obtained from ground based observations of radio emissions²⁻⁶.

A second opportunity to study the main magnetic field of Jupiter occurred on December 3, 1974, when Pioneer 11 passed within $0.6R_J$ of the planetary surface. The near planet trajectory is shown in Fig 1, presented in a magnetic latitude and distance format using the assumed D_2 model field⁷. The wide excursion in latitude is accompanied by a similarly wide coverage in longitude, extending 660° from $\lambda_{III}=30^\circ$ at 0000 GMT to $\lambda_{III}=330^\circ$ at 1100 GMT.

A high field magnetometer was placed on Pioneer 11 by NASA-GSFC to provide extended range coverage up to 17 gauss, values believed representative of high latitude, low altitude field intensities from radio astronomy observations²⁻⁶. Here we present the preliminary results of an analysis of quick-look data obtained from this instrument. We find that within $3R_J$, the planetary magnetic field is much too complex to be represented by a simple OTD and that higher harmonic multipoles are required.

The instrumentation aboard Pioneer 11 consisted of a single range triaxial fluxgate magnetometer capable of measuring fields up to 10 gauss along each orthogonal axis, and associated electronics. The quantisation step size for the 10-bit A/D converters used is ± 600 gamma for fields less than 2 gauss. An instantaneous vector measurement of the magnetic field is obtained once every three revolutions of the spacecraft (36 s) when a reference axis crosses through the ecliptic. The magnetometer weighs 272 g and uses 0.3 W of power from the GSFC Cosmic Ray Telescope Experiment. A more complete description is given in ref. 8.

The raw magnetic field data are translated to a Jupiter centred spherical coordinate system and combined with spacecraft trajectory information to yield a measurement

Fig 2 Comparison of expected magnetic field of Jupiter (solid line) assuming simple offset tilted dipole magnetic field model with observations (circles) by GSFC high field triaxial fluxgate magnetometer. Period of occultation of radio transmission of data indicated by OC. Spacecraft-centred inertial cartesian coordinates are used (z axis points to Sun, x axis points to south ecliptic pole).

Fig 3 Isointensity contour map of magnetic field on surface of Jupiter predicted by GSFC model O₁, using 15 spherical harmonic coefficients up to octupole moment. Field strength of each contour given in gauss. Trace of sub-Pioneer 11 point, at time (GMT) on 3 December, is indicated accordingly (four digit numbers). For Io footprint, equal 20° longitude increments at Jovigraphic latitude = 0° and radial distance = 5.95R_J were used as starting points. Note significant distortion of field lines from meridian planes. —, Footprint of field line through Io, — — —, sub-Pioneer 11 trace, - · - · -, magnetic equator

set. Conversely, given a magnetic field model, we can obtain the equivalent readings which should be observed in each orthogonal axis of the instrument coordinate system. This is illustrated in Fig 2 where the theoretical digital counts expected from the D_2 model are plotted along the Pioneer 11 trajectory (solid line) and compared to the observations (circles). For radial distances greater than $3R_J$, there is reasonable agreement with the predicted values but closer to the planet, the field magnitudes increase rapidly, much faster than the expected inverse cube law for a dipole. This implies the existence of higher order multipoles, which become very significant for distances smaller than $3R_J$.

The observations between 1.7 and $5.6R_J$ have been fitted in a least squares sense to first, second and third degree spherical harmonic expansions—terms corresponding to a centred dipole, quadrupole and octupole moments. We find a significant decrease in the root mean square (r.m.s.) of the residuals when quadrupole and octupole terms are included. An offset tilted dipole representation, which uses six of the eight dipole plus quadrupole coefficients, yields a vector r.m.s. of 0.026 gauss which is considerably larger than the quantisation step size of the instrument, whereas an octupole expansion, using 15 coefficients, reduces the r.m.s. value to 0.019 gauss. This is a clear indication that the main field of Jupiter is much too complex to be represented by an OTD, especially for $R < 3R_J$.

To illustrate the complexity of the field topology near the planet, the surface field derived from the 15 coefficient spherical harmonic expansion, that is, terms up to and including an octupole, has been plotted in the form of iso-intensity contours as shown in Fig 3. The field strength at the poles is asymmetrical and much larger, 17 and 13 gauss in the north and south respectively, than that obtained from OTD representations. The magnetic equator, as defined by the zero dip angle, is highly distorted with respect to the Zenographic equator. Some caution must be exercised in the interpretation of these results since they represent only one solution of many possible fits to the observations along the spacecraft trajectory. This means that inclusion of higher order multipoles and/or a different data interval lead to a modified coefficient set. Nevertheless, the contribution of higher order multiple terms is evident, independent of the particular expansion used to derive the surface field. Thus, the differing results obtained in separate studies of the radio

emissions may be capable of being resolved in terms of different source locations and the sensitivity of the interpretation to distortion by non-dipole terms.

The iso-intensity surface map in Fig 3 shows many unique features. Most remarkably, the 'footprint' of the field line through the satellite Io passes near both the north and south magnetic dipole regions. So particles mirroring on the L shell of Io also mirror in the Zenovian auroral regions. The hemispherically asymmetrical field leads to uniquely asymmetrical mirror points for such trapped particles. The field intensities in the polar regions are now high enough to allow further elaboration and detailed study of the relationship of decametre emissions by Jupiter and their modulation by Io^{2-6} . The longitude of the north polar region, $205 \pm 15^\circ$, is quite consistent with much prior work²⁻⁶. These four features suggest to us that the source of decametre radio emission from Jupiter is sporadic precipitation of particles into the Zenovian auroral regions. Although the distortion of the magnetic equator is large at the surface, we find that it rapidly approaches a simple OTD model at $R > 2.5R_J$. The dipole terms of the OTD correspond to a dipole moment of 4.2 ± 0.1 gauss R_J^3 at a tilt angle of $8.5 \pm 1.0^\circ$ and a longitude $= 225^\circ \pm 10^\circ$.

The motion of charged particles in such a non-axially symmetric field configuration means that a further complexity is added to the interpretation of such observations. Indeed, it is these asymmetries which also suggest to us that the reason for the 10-h periodicity^{9-12,13} in charged particle observations on Pioneer 10 depends in part on a special azimuthally asymmetric magnetospheric configuration. Thus, a particular field geometry occurs only once every Jovian rotation, rather than the twice which is demanded by any nearly axially symmetrical model such as an OTD with small offset.

We believe that these results and the derived quantitative octupole model of the main magnetic field of Jupiter will permit reconciliation of the previous 20 yr of radio astronomy data with the real magnetic field of Jupiter. Moreover, with the *in situ* charged particle observations by Pioneer 10 and 11, an understanding of the basic source mechanisms and processes leading to the suite of emission phenomena should now be possible.

New microstructure of decametre solar radio bursts

THE fine structure of a variety of decametre solar radio bursts obtained with high temporal and frequency resolution spectrographs provides valuable information on the generation mechanisms of these bursts together with the physical conditions in the corona. Earlier observations¹⁻¹⁰ of solar radio bursts in the decametre region have revealed some types of fine structure bursts, drift pairs and split pairs being examples of fine temporal and frequency structure bursts respectively.

We report here a new type of solar decametre bursts which, we believe, has been seen for the first time. This was a result of high resolution (frequency ~ 5 kHz and time ~ 10 ms) spectral observations made over a frequency range of only 0.5 MHz near 35 MHz with a scanning rate of 100 Hz. A circularly polarised crossed-Yagi antenna with an effective gain of about 8 db was used to track the Sun. Recording was on a continuously moving 35-mm film.

This high resolution spectroscope, went into regular operation in February, 1974. Since then a large number of solar radio bursts, including a variety of fast drift bursts (individual, in large groups, as well as storm bursts) have been recorded. Three noise storm periods, one each in July, August and September, 1974, were interesting.

Figure 1a and b shows examples of a new class of bursts which occurred respectively on July 17 and August 6, 1974. Each of the bursts, which we call 'complementary bursts' is characterised by two components, the first of which is essentially a fast drift burst comprising patches of strong and weak emissions (or emission gaps). After a time delay of ~ 0.5 s, narrow bands of intense emission are seen to have occurred. They cover a frequency range of ~ 30 –70 kHz which is almost equal to the one corresponding to the emission gap in the first component. Figure 1c shows another event which occurred on July 16, 1974. Here the intense emission in the second component covered a range of ~ 350 kHz against the very weak emission in the first component. Again, the time delay between the two components was ~ 10 s.

Figure 1d shows another example of this type of burst. This event was recorded on September 13, 1974. It is interesting that there are three components in this burst. Furthermore, in this case there is an intense narrow band emission in the second component corresponding to the emission gap in the first component, and corresponding to the emission gap in the second component there is an intense narrow band emission in the third component. These examples show that, in general, the frequency drift rates of these narrow band emissions are less than those of their first components. In particular, the drift rates are higher if the intercomponent time delay is more (Fig 1c).

Thirty four 'complementary bursts' were recorded from July through September, 1974. On average, two different groups of delays between the components of bursts are observed. The duration, at a given frequency, of all the components is ≤ 1 s. Figure 2 is a histogram of the time delay between the components of bursts and the number of bursts. It shows two delay groups centred around 1–2 s and 10–15 s. The emission gap for the first group covers a frequency range of about 30–70 kHz. For the second group it covers a range of about 100–200 kHz. Again, the delayed narrow band emissions of the bursts show frequency drift rates of ≤ 500 kHz s⁻¹ for the bursts with the intercomponent delays of 1–2 s and ≥ 1 MHz s⁻¹ for the bursts with 10–15 s intercomponent delays.

The phenomenon described here could possibly be the result of either the same stream of electrons, or to two or three successive electron streams. In the case of more than one stream, the first stream, while moving out through a smooth

coronal plasma in which the conversion of plasma waves into transverse electromagnetic waves is very poor, might excite only sporadic emissions. Such a stream might create some turbulence behind it. The next stream, which encounters such a turbulence, should give rise to a continuous type III emission which is not what is observed. It is thus difficult to imagine how the intense narrow band emissions in the later components could occur only over the frequency range corresponding to which there are emission gaps in the previous component. The possibility of successive streams was invoked to explain type IIIb associated with type III bursts⁶.

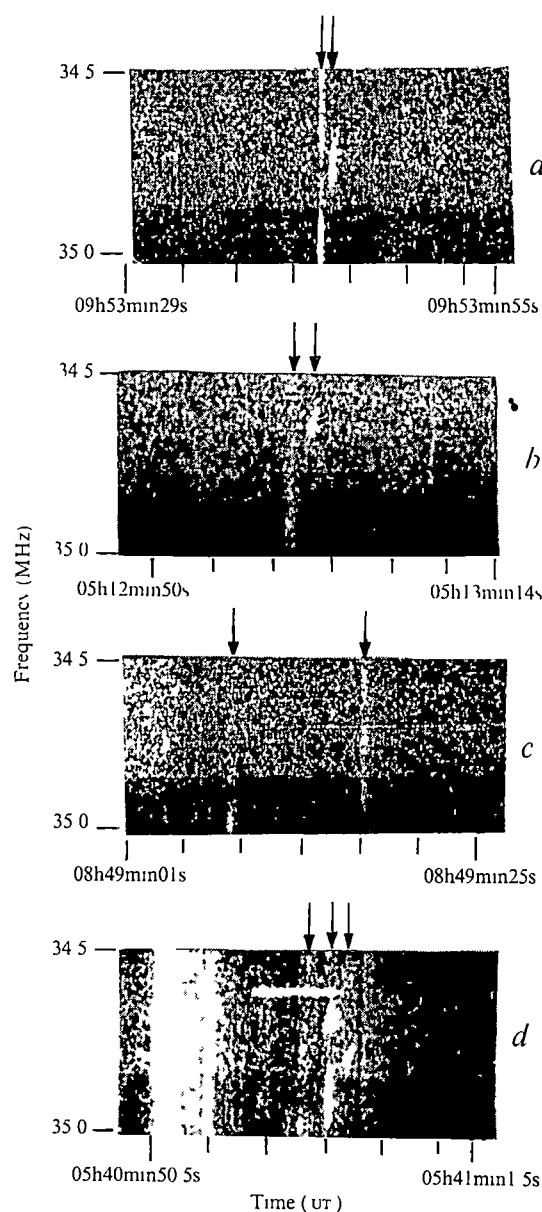

Fig 1 Dynamic spectra of solar bursts near 35 MHz. a, Burst on July 17, 1974 showing two components (marked by arrows above), the first with an emission gap around its centre, the second strong and delayed by ~ 0.5 s. b, Similar event on August 6, 1974. c, Burst on July 16, 1974, the second bright component is delayed by ~ 10 s. d, Bursts on September 13, 1974. The bright vertical patch is a group of type III bursts. The next event shows three components displaying similar characteristics as the two-component events. Horizontal bright line is due to a local transmission. The lower dark strip in each photograph is due to receiver gain variation of ~ 1 db.

Fig 2 Histogram showing the number of bursts as a function of time delay between their components. Total number of bursts $n = 34$ observed from July through September, 1974. Note the two delay groups, one around 1–2 s and the other around 10–15 s.

On the other hand, if a single stream model is assumed the sporadic emissions of the first component may be due to the sporadic leakage of electrons moving along a coronal streamer. The narrow band emissions in the following components may then occur due to the electrons which propagate at an angle with the streamer. The region where this happens might be the region of a discontinuity at the interaction of the streamer with another coronal structure moving with a different velocity¹¹. The observed slower frequency drift rates of these narrow band emissions then depend on the angle between the direction of propagation of these electrons and the plasma density gradient in these magnetically turbulent regions¹². It is also possible that the narrow band emissions could be the result of transmission characteristics of the propagation medium which acts like a band-pass filter. But this does not explain why the narrow band emission of the second component always corresponds with the emission gap in the first component. We must, therefore, think in terms of duct-like coronal structures which trap and delay part of the electromagnetic radiation of the first component, analogous to terrestrial whistler mode propagation. White light coronagraphs of coronal loop structures lasting for less than an hour and observed over distances from 1.5 to 6 solar radii were made during the Skylab mission¹³. These structures may provide the necessary trapping ducts.

The narrow band emissions in the second component of these bursts are relatively more intense. If these emissions are due to the acceleration of electrons in the coronal structure interacting with the coronal streamer, then one should invoke a process whereby the amplitude of the intensity of these emissions is built up.

We note that these complementary bursts are a distinct class by themselves in the sense that there is no association between them and type III bursts. Clearly this is different from the association between type IIb and type III bursts wherein the former occurs as a precursor to the latter⁶.

The frequency structures that have been reported here as complementary bursts cannot be attributed to the effect of Faraday rotation since our antenna is circularly polarised.

Polarisation observations of this type of bursts would be rewarding. So a provision is being made in the spectroscope for making observations of right and left circular polarisation.

We thank Professor K. R. Ramanathan and Mr S. K. Mattoo for discussions and Mr R. Sharma for assistance in developing the antenna. Financial support was provided by the Department of Space, Government of India.

Storm-time increases in the ionospheric total electron content

CHANGES in the total electron content of the mid-latitude ionosphere during the first day of each of 20 geomagnetic storms have been monitored by Papagiannis *et al.*¹ They have shown that during the positive phase of the storms the magnitude of the increase in total electron content exhibits a very pronounced maximum near sunset. Although Rishbeth and Hanson² have shown that plasma convergence in the F region itself cannot account for the observed increases, an inward meridional $E \times B$ drift of the plasma may compress the H^+ gas at great heights^{1,2}, giving rise to a field-aligned flow of H^+ into the ionosphere. We have investigated the consequences of field-aligned H^+ flow by integrating the F region–protonosphere equations of motion and continuity for O^+ and H^+ along magnetic tubes that are undergoing $E \times B$ drift. The range of integration is from the lower F region to the equatorial crossing point of the magnetic tube, the method of integration being essentially that of Moffett and Murphy³. Our results support the idea that an influx of ionisation from the protonosphere may be partly responsible for some storm-time increases in ionosphere content.

An important feature arising from our investigation is the relationship between the meridional $E \times B$ drift of the plasma and west-east $E \times B$ drift relative to the Earth. This relation results from the assumption of an incompressible magnetic field. Rishbeth and Hanson² and Murphy⁴ have shown that for a dipole field, at the equatorial crossing point of the field line,

$$\nabla v_{em} = 6v_{1eq}/r_{eq} \quad (1)$$

where v_{1eq} is the value of the meridional component of $v_{em} = E \times B/B^2$ at the equatorial crossing point (v_{1eq} being positive in the radially outwards direction) and r_{eq} is the geocentric distance of the equatorial crossing point. The derivation of this expression requires the conditions $\nabla \times E = 0$ and $\nabla \times B = 0$. The first of these arises from conservation of the magnetic field. The second is consistent with the dipole field approximation and is justifiable provided electric currents are small enough. Note that equation (1) is correct even if a west-east drift occurs, as will usually be the case.

Fig 1 Plots of the O^+ content in a tube with base area 1 cm^2 at 200 km and of the downward H^+ flux through the $1,000\text{-km}$ level as a function of equatorial crossing height, z_{eq} , of the magnetic tube —, Results when $L = 4.0$ initially, ---, results when $L = 3.5$ initially. The plasma temperature at the equatorial crossing point is always $\leq 6,000 \text{ K}$, no account is taken of the increase in temperature that will arise from plasma compression. The numbers on the curves give the local time (min) that has elapsed since the tube started drifting

An alternative expression for ∇v_{em} can be derived by resolving v_{em} in the meridional and west-east directions

$$v_{em} = v_{\perp} \hat{n} + v_{\phi} \hat{\phi} \quad (2)$$

where \hat{n} is a unit vector normal to \mathbf{B} in the meridional plane and $\hat{\phi}$ is a unit vector in the west-east direction, ϕ being the local hour angle and also the azimuthal angle of spherical polar coordinates. At the equatorial crossing point of the field line this alternative expression takes the form^{5,6}

$$\nabla v_{em} = \frac{4v_{\perp}^{eq}}{r_{eq}} + \frac{\partial v_{\perp}^{eq}}{\partial r_{eq}} + \frac{1}{r_{eq}} \frac{\partial v_{\phi}^{eq}}{\partial \phi} \quad (3)$$

where v_{ϕ}^{eq} is the value of the west-east plasma drift velocity relative to the Earth at the equatorial crossing point

Equating equations (3) and (1) gives

$$\frac{\partial v_{\phi}^{eq}}{\partial \phi} = 2v_{\perp}^{eq} - r_{eq} \frac{\partial v_{\perp}^{eq}}{\partial r_{eq}} \quad (4)$$

The significance of equation (4) for our purpose is that a uniform, inward meridional drift (giving a negative v_{\perp}^{eq}) tends to make v_{ϕ}^{eq} negative. A negative value for v_{ϕ}^{eq} means that the plasma is rotating more slowly than the Earth. The time taken by the plasma to drift from a position with a particular hour angle ϕ_1 to a position with a later hour angle ϕ_2 may be much greater than the local time between ϕ_1 and ϕ_2 . If a downward field-aligned flux from the protonosphere is caused by an inward drift, then the effect of this flux on the F region is magnified by the increase of time available for a given observing period of local time.

Equation (4), of course, gives only the rate of change of v_{ϕ}^{eq} , the value of v_{ϕ}^{eq} when the inward drift commences is important. In our calculations we have arbitrarily taken $v_{\phi}^{eq} = 0$ at the start of the inward drift, since indeed a negative initial value for v_{ϕ}^{eq} would increase the local-time effects of the downward H^+ flow.

We adopted a time-independent Jacchia model atmosphere, with an exospheric temperature of $1,000 \text{ K}$. The linear loss coefficient for O^+ at 300 km was $3.2 \times 10^{-4} \text{ s}^{-1}$ and a horizontal

equatorward wind in the neutral air with velocity 150 m sec^{-1} was assumed. The concentration of neutral hydrogen at 400 km was taken to be $10^5 \text{ atoms cm}^{-3}$ and the rate coefficient for H^+-O charge transfer to be $1.4 \times 10^{-9} \text{ cm}^3 \text{ s}^{-1}$ (ref 7, and E E Ferguson, private communication). Typical values of electron and ion temperatures for heights less than $1,000 \text{ km}$ were taken from Brace *et al*⁸ and Evans⁹. We have pointed out (in a paper to be published) that increases in T_e and T_i at great altitudes tend to increase the downwards field-aligned flow of H^+ , and it has been noted by Rishbeth and Hanson² that inward $\mathbf{E} \times \mathbf{B}$ drift will tend to heat the plasma by compression. We have chosen to take, above $1,000 \text{ km}$, T_e equal to T_i and a temperature gradient with height of 2 K km^{-1} until a temperature of $6,000 \text{ K}$ is reached. An estimate of the compression heating shows that this is a very conservative value for the plasma temperature at great altitudes. Possible production of O^+ by photoionisation of atomic oxygen was ignored, so that any increases in O^+ content may be ascribed to influx of H^+ .

In our investigation we examined the behaviour of the plasma in two tubes of plasma. One tube (tube 1) underwent $\mathbf{E} \times \mathbf{B}$ drift from $L = 3.5$ to $L = 2.8$, the other (tube 2) from $L = 4.0$ to $L = 2.8$. In both cases the plasma was given a meridional drift velocity of $v_{\perp}^{eq} = -1 \text{ km s}^{-1}$. This value is based on the work of Park¹⁰. He has interpreted whistler observations of the draining of H^+ from tubes of plasma during and after a magnetic storm as evidence for inward drift of the tubes. The initial value of O^+ content above 1 cm^2 at 200 km was $5.8 \times 10^{12} \text{ cm}^{-2}$ in both tubes. The initial O^+ contents in the tubes were taken to be identical to isolate $\mathbf{E} \times \mathbf{B}$ compression effects from those arising from spatial gradients in electron concentration in the F region that may initially be present. It should be noted that Rishbeth and Hanson² have suggested that concentration gradients in the F region at initial L values of the tubes may contribute to the storm increases seen at lower L values. Our initial H^+ contents were proportional to the volumes of the tubes.

If the tubes start drifting at local time $t_0 = 0$, tube 1 arrives at $L = 2.8$ (the L value of the observations in ref 1) at local time $t_1 = 1 \text{ h}$, whereas tube 2 arrives at $L = 2.8$ at local time $t_2 = 1 \text{ h } 30 \text{ min}$. It is found that at $L = 2.8$ the O^+ content in tube 1 is $2.62 \times 10^{12} \text{ cm}^{-2}$ and in tube 2 $3.72 \times 10^{12} \text{ cm}^{-2}$. Thus an observer at $L = 2.8$ will see during local time $t_2 - t_1 \approx 30 \text{ min}$ an increase of $1.1 \times 10^{12} \text{ cm}^{-2}$ in O^+ tube content. Figure 1 shows the behaviour of the plasma in the flux tubes as a function of L value as we follow the tubes.

This result demonstrates at least that, in discussion of magnetic storm increases, ionisation flow from the protonosphere must be taken into account when inward $\mathbf{E} \times \mathbf{B}$ drift occurs.

Precambrian geomagnetic field reversal

THE geomagnetic field has reversed many times. Numerous polarity transitions of Cainozoic age, together with very few of Mesozoic and Palaeozoic age, have been studied in detail and the studies indicate that the processes involved have remained relatively unchanged in time. Here we report the first detailed study of a Precambrian reversal.

As part of a palaeomagnetic survey (D K B, M E E, A B Reid, and E W McMurry, unpublished) of Proterozoic sediments in the East Arm Fold Belt of Great Slave Lake, 45 stratigraphically distinct sites have been sampled across a continuous 600-m section. The section consists of steeply dipping, finely bedded, red siltstones in the lower part of the Stark Formation of the Great Slave Supergroup¹. Available K/Ar dates from associated intrusive bodies place the Stark Formation in the age range 1,650–1,800 Myr (ref 1) though palaeomagnetic data may indicate a slightly younger age (D K B, M E E, and E W McMurry, unpublished). Lithologically, the section is very uniform except for many fine green bands which were generally avoided during sampling. Detailed palaeomagnetic studies using thermal and alternating field treatment indicated a marked uniformity in the magnetic properties, all of the specimens are very hard magnetically and possess well defined haematite Curie points.

We have not found any strong evidence that the remanence is primary. It is possible that the red beds could have been remagnetised when they were reheated during the emplacement of the nearby MacKenzie intrusions about 1,200 Myr BP (ref 2). Our observations do not, however, support that idea. The intrusions were emplaced after the folding of the Great Slave Supergroup and the palaeomagnetic pole which we have obtained is 70° from the MacKenzie pole before bedding corrections are applied. As the MacKenzie intrusions represent the most recent igneous event in the East Arm Fold Belt it seems that the red beds acquired their remanence before 1,200 Myr BP. Other workers³ have reached the same conclusion regarding the possible remagnetisation of other red beds in the East Arm Fold Belt. Furthermore, the presence of a reversal and transition zone such as that described here

Fig 1 Stratigraphic profile of thermally cleaned, site mean directional and site mean intensity data for the Stark Formation, after correction for geological dip. Each site is represented by 2, 3 or 4 samples. *a*, Remanent intensity (J), *b*, inclination below horizontal, *c*, declination east of true north. Error bars indicate the standard error of the mean. Dotted line, five-point running mean of J omitting two non-red sites which gave consistent, though weak, results.

Fig 2 Virtual geomagnetic poles from the Stark Formation after dip correction. Triangles, stable normal (19 sites) and reversed (20 sites) poles with 95% ovals of confidence, circles, intermediate poles. Square is sampling location. Closed (open) symbols and solid (dashed) lines are on the Northern (Southern) Hemisphere. Wulff net.

indicates that secondary components of magnetisation which post-date the initial magnetisation are not significant⁴. We therefore feel that it is reasonable to assume that the magnetisation is primary.

The most prominent features of the thermally cleaned site mean directions and intensities (Fig 1) are the polarity reversal which occurs about mid-way through the section and the apparent field excursion in the lower third of the section. We assume that the remanent intensities are log-normally distributed^{5,6}, and we have shown geometrical means and the associated standard errors. This assumption is, however, not critical as the arithmetical means lead to the same conclusions. Figure 2 shows the corresponding virtual geomagnetic poles (VGPs) for the reversal and excursion, only the overall means for the rest of the section are indicated. A number of features of the reversal are immediately apparent: (1) it occurs across approximately 25 m of section (Fig 1 *b* and *c*), (2) an approximately great circle path is followed by the transitional VGPs (Fig 2), (3) the pre- and post-transitional VGPs are essentially antipodal (Fig 2), (4) the remanent intensity decreases by a factor of 2 or 3 within the transition zone (Fig 1 *a*), (5) the reduction in intensity covers approximately the same time interval as the reversal in direction, though there is a suggestion of reduced but perhaps unstable intensity just above and below the transition zone (Fig 1 *a*).

The field excursion occurs across about 5 m of section approximately 150 m below the reversal (Fig 1). It represents an excursion by the palaeopole of about 80° from the stable direction above and below it, and the VGP of the excursion lies close to the great circle described by the path of the transitional VGPs (Fig 2). There is a suggestion of reduced and unstable remanent intensity in the vicinity of the excursion but the excursion itself does not show reduced intensity (Fig 1).

Accepting the appropriate sedimentation rates given by Kukal⁷ the transition covers 10⁴–10⁵ yr, which implies that either the reversal took considerably longer than the 1,000–2,000 yr observed for more recent transitions⁸ or that the sedimentation rate was a factor of 10–100 higher than expected, or some combination of these two alternatives. The excursion occurred across only 5 m of the section, which—if the sedimentation rate was constant, as is suggested by the uniform lithology—

represents less than 1/5 of the time taken for the transition to occur

The great circle pole path, the antiparallelism of the transition, and the reduced intensity are features common to many but not all of the more recent reversals which have been studied in detail⁹⁻¹⁴. The relationship between the remanent intensity of rocks and the palaeointensity of the geomagnetic field is not necessarily simple. The uniformity of the section both lithologically and magnetically suggests, however, that the coincidence of the reduced remanent intensity with the transition zone is more than accidental. The use of thermally cleaned results in this context is not critical as the uncleaned intensity profile exhibits the same major features.

These observations are relevant to a discussion of the mechanism of geomagnetic field reversal. There are two extreme possibilities: decay and subsequent antiparallel re-establishment of the dipole field, or a 180° dipole 'flip' with no change in strength. The palaeolatitude of the sampling site is 8°, and abundant halite casts offer independent evidence of a tropical climate. At such low latitudes a 'flip' reversal could give rise to a spectrum of intensity profiles ranging from no change to an increase by a factor 2, depending on the meridian followed by the pole. In the present case the transitional pole path passes close to the sampling site and an increase in intensity could therefore be expected. The clear minimum actually observed thus provides strong evidence of a real decrease in the dipole moment during the reversal.

Several workers¹⁵⁻¹⁷ have noted that the period of reduced intensity during recent polarity transitions is longer than the time needed for the direction to reverse, although others have found that these periods coincide¹⁸. It is difficult to place this Precambrian reversal in either class but there is a suggestion of very rapid variations in intensity immediately before and after the change of direction, such as has been seen in more recent reversals¹⁹.

The term 'field excursion' or 'systematic deviation' is usually applied to short duration deviations in pole position, which are greater than 40° or 50° but significantly less than 180° and which are not immediately associated with field reversals²⁰⁻²². The field excursion reported here fits this description but we stress that it is represented by a single site mean. The reduced and/or unstable intensity near the excursion supports findings^{21,23-25} which correlate low latitude poles with reduced intensity.

Perhaps the most significant point about the field excursion is its location near the transition pole path, which suggests that, though it occurred a significant time before the reversal, it is perhaps not wholly unrelated to it. Some coincidence of great circle paths described during several separate reversals⁹ and during distinct field excursions²⁵ has been observed in the recent palaeomagnetic record. The result reported here is consistent with these results and with the hypothesis that field excursions represent aborted reversals²⁰. It also provides support for the existence of long lived non-dipole sources²⁵ or stable equatorial dipoles⁹.

Whatever is the exact mechanism involved in geomagnetic field reversals—dipole decay or dipole flip-over, or a combination of these—the data reported here indicate that the process has apparently remained essentially unchanged for nearly 2×10^9 yr of the Earth's history. The only significant difference involves the possibility that the transition occupied a considerably longer time interval than more recent reversals⁸. These observations place additional limits on the history of the geomagnetic field and, by implication, the thermal evolution of the Earth's core.

Search for compression before a deep earthquake

DZIEWONSKI and Gilbert¹, using a moment tensor representation of the seismic source, presented evidence for precursive compression before deep earthquakes. For the Colombian earthquake of July 31, 1970 (17 08 05 4 GMT, 1 5° S, 72 6° W, $h > 650$ km), they concluded that a large precursive compression occurred in the focal region, beginning about 80 s before the origin times as determined by ordinary P wave travel times.

These results were, however, obtained from data derived from free oscillations with periods longer than 70 s, and so the time resolution is inevitably limited. Moreover, the phase information contained in the free oscillation data is somewhat obscured by the lateral heterogeneity of the Earth. It is therefore important to search for the existence of precursors by using an independent set of data. Thus, we have examined carefully the direct displacement field caused by a precursor. Specifically, we examined seismograms of the Colombian earthquake of July 31, 1970 and compared these observations with synthetic seismograms of the proposed precursor (Figs 1-4).

The epicentre of the July 31 earthquake is located relatively close to roughly a dozen World Wide Standard Seismograph Network (WWSSN) stations and also close to a station at Naña, Peru. The stations all lie between 6 07° and 16 0° from the epicentre. The wavelength of such a slow precursor is about 1,000 km, and so the Earth can be modelled by a homogeneous medium for our synthetic seismogram computations at these short distances.

For a contraction source with time function $\chi(t)$, the radial displacement in the medium is given² by,

$$u_r = \frac{M}{4\pi\rho\alpha^2} \frac{d}{dr} \left(\frac{1}{r} \chi(t-r/\alpha) \right) \\ = \frac{-M}{4\pi\rho\alpha^2} \frac{1}{r^2} \left[\chi(t-r/\alpha) + \frac{r}{\alpha} \chi'(t-r/\alpha) \right] \quad (1)$$

where α =compressional velocity, ρ =density, r =radial distance, and M =moment of inertia.

The first and second terms in the brackets represent the near-field and far-field displacements, respectively. The time function

of the proposed precursor can be described adequately by the function

$$\chi(t) = \begin{cases} 0 & t \leq -\tau_1 \\ \frac{1}{\tau_1 + \tau_2} \left[t + \frac{\tau_1}{\pi} \sin \frac{\pi}{\tau_1} t + \tau_1 \right] & -\tau_1 \leq t \leq 0 \\ \frac{1}{\tau_1 + \tau_2} \left[t + \frac{\tau_1}{\pi} \sin \frac{\pi}{\tau_2} t - \tau_1 \right] & 0 \leq t \leq \tau_2 \\ 1 & t > \tau_2 \end{cases} \quad (2)$$

where τ_1 is the precursor time constant, τ_2 the time constant of the post-seismic deformation, and $t = 0$ refers to the 'origin time'. This time function avoids discontinuities in displacement, velocity and acceleration at both $t = \tau_1$ and $t = \tau_2$, and represents one of the smoothest time functions for a given time constant. Substituting this time function into equation (1), doubling the result to account for the free surface effect, convolving it with the appropriate instrument functions, and including the necessary cosine factors to account for the azimuth and angle of incidence terms, we obtain the synthetic seismograms. In our present computation we used $M = 5.0 \times 10^{27}$ dyne cm, the value suggested by Dziewonski and Gilbert¹, $\alpha = 8.5 \text{ km s}^{-1}$ and $\rho = 3.5 \text{ g cm}^{-3}$ for the average upper

Vertical *a*, observed, *b*, synthetic N-S, *c*, observed, *d*, synthetic BOG records. peak magnification = 3,000, $\Delta = 6.23^\circ$, *e*, observed, *f*, synthetic. Arrows next to the synthetic traces indicate precursor onsets.

mantle. For τ_1 and τ_2 , we consider three cases: (1) $\tau_1 = \tau_2 = 80 \text{ s}$, the value for the precursory time constant suggested in (the abstract of) Dziewonski and Gilbert¹, (2) $\tau_1 = 120 \text{ s}$, and $\tau_2 = 160 \text{ s}$, in this case, $d\chi(t)/dt$ matches the isotropic moment rate tensor suggested by Dziewonski and Gilbert¹ (Fig. 5), and (3) $\tau_1 = \tau_2 = 160 \text{ s}$, this last case represents a more gradual precursor which Dziewonski and Gilbert (personal communication) have suggested might be more appropriate (see Fig. 5).

Long period, vertical seismograms from five WWSSN stations—ARE, BOG, CAR, LPB, and QUI—were available to us. Long period, horizontal records from three of these stations—ARE, LPB, and QUI—were also examined. These seismograms and the corresponding synthetic seismograms are shown in Figs 1, 2, and 3. Recordings of the long period strain network and of the vertical pendulum seismometer at Naña, were also used in our investigations. These records and the respective synthetics are shown in Fig. 4. The very long period information on the strain record indicates tidal strains and some minor surface wave effects from an earlier earthquake in the South Pacific. Neither of these strains was included in the

synthetic strain record The observed strain record has been fitted with a parabola for the 80 min preceding the onset of the main phase which closely approximates the tidal period The synthetics for case (1) predict very large precursor amplitudes, as much as 6 cm peak to peak, on a WWSSN instrument operating at a peak magnification of 3,000 We were, however, unable to identify any trace of such an arrival on any of the

Fig 3 Long period, WWSSN seismograms *a-d*, LPB records peak magnification=1,500, $\Delta=15.61^\circ$ Vertical *a*, observed, *b*, synthetic N-S *c*, observed, *d*, synthetic CAR records Peak magnification=3,000, $\Delta=13.15^\circ$, *e*, observed, *f*, synthetic Arrows next to the synthetic traces indicate precursor onsets

ten seismograms examined Thus, if the precursor time constant is 80 s, the moment must be much less than that assumed here, probably less than 5.0×10^{26} dyne cm For case (2), since the response curve for the Naña strain network is almost flat for $T < 600$ s, the predicted amplitude is reduced only 30% from case (1) (Fig 4A) In the case of the WWSSN instruments, however, we are dealing with the steep portion of the response

Fig 4 A, Observed (*a*) and synthetic (*b*) strain records for the Caltech north-east strain network at Naña, Peru Tidal effects removed from the synthetic Small arrow indicates precursor onset, $\Delta=11.21^\circ$ Note the change of time scale between this figure and the preceding three B, Observed (*a*) and synthetic (*b*) seismograms for Caltech vertical pendulum seismometer at Naña, Peru Arrow indicates precursor onset, $\Delta=11.21^\circ$ Note that the polarity is reversed

curve (ω^3) and the amplitude is greatly reduced by the increase in τ_1 from 80 to 120 s Nevertheless, two nearby stations, QUI ($\Delta = 6.07^\circ$) and BOG ($\Delta = 6.23^\circ$), still show significant amplitudes (Figs 1 and 2) Thus, on the basis of Naña, QUI and BOG, we may conclude that the isotropic moment must be significantly smaller than the suggested value, probably less than 10^{27} dyne cm For case (3), the precursor signal is almost undetectable at all stations except Naña where the signal is still significant (Fig 4A) If the precursory time is longer than about 200 s, the proposed isotropic precursor would be hardly detectable This time constant is somewhat longer than that suggested by Dziewonski and Gilbert¹, but in view of the discrete time interval of about 40 s used by them it might be within the permissible range

We conclude that if the precursor time constant is less than 120 s, the isotropic moment must be less than 10^{27} dyne cm or, if the precursor moment is 5.0×10^{27} dyne cm, the lower bound of the precursor time is 200 s

One of us (R S H) thanks the National Science Foundation for Graduate Fellowship support We thank Professors Dziewonski and Gilbert for their comments on this manuscript

DRS DZIEWONSKI AND GILBERT REPLY—We have stated that for two deep earthquakes the hypocentral region begins to experience compression about 80 s before the origin time determined from the first arrivals of P waves. This statement was based on an estimate of the time at which the isotropic moment rate begins to exceed the noise level visible in the deviatoric part of the moment rate tensor (Fig 2 of ref 1). The figure shows that isotropic moment rate is other than zero at times earlier than -80 s, and obviously our estimates of the "beginning" time could not have the meaning that Hart and Kanamori assigned to it.

Our measurements were carried out in the frequency domain. Transformation to the time domain required certain arbitrary, although clearly stated, assumptions because the spectrum was incomplete and contained noise. In these circumstances, if one attempts to introduce an analytical source function, the matching of the parameters should be done in the frequency domain. For the source function proposed by Hart and Kanamori² and the isotropic moment rate spectrum shown in Fig 1 the best match is for a time constant of 160 s, a time constant of 200 s is also consistent with the data if M_0 is allowed to increase by 50%. In either case the amplitudes of the synthetic seismograms would approach the noise level (the amplitudes would decrease by a factor comparable to that resulting from the increase of a time constant from 80 to 120 s).

It is disappointing that the result of the experiment by Hart and Kanamori is inconclusive, because it seems that with the present instrumentation it may be impossible to

confirm by observations in the time domain the occurrence of precursory phenomena such as those described in our paper¹, the Colombian earthquake was the largest event in its depth range during the past 12 yr. Such confirmation would be very important, as at the present time we must rely on the assumption that the observed spectra should be smoothly interpolated to zero frequency. If this assumption were not valid, then compression might not be precursive. The most important result of our paper¹, which is not subject to this assumption, is that there are volume changes associated with deep earthquakes and that their time function must be significantly different from that of the deviatoric (shear) moment tensor.

In the paper by Hart and Kanamori² we notice a long-period trend in the observed seismograms shown in Fig 1a and c and Fig 2c and e that agrees with the sign predicted by the theoretical calculations, that is, is consistent with the hypothesis of precursory compression. The same is true for a deflection on the strainmeter recording that occurred just before the earthquake (The steeply rising pulse immediately following $t = -\tau_1$ on the theoretical seismograms is determined by the properties of the source function at $t = -\tau_1$. This effect could be substantially reduced if Hart and Kanamori had chosen a function that has a more gradual rise.) Even though none of these examples is significant by itself, the fact that there are several of them is intriguing, particularly as there are no adverse cases.

Chemistry and origin of phlogopite megacrysts in kimberlite

STUDIES of the megacrysts occurring in kimberlite have hitherto neglected the mica megacrysts. We have analysed mica megacrysts from one Lesotho and twelve South African kimberlites. The megacrysts, which vary in size from 4 mm to 3 cm, were taken from both 'basaltic' and micaceous kimberlites, and distinguished from the matrix phlogopites by (i) their greater size, (ii) their dark brown, rather than bronze or light brown, colour, (iii) their rounded shape and corroded margins, (iv) distortion of the {001} planes (in some, but not all, megacrysts), and (v) absence of inclusions of matrix phases such as perovskite and spinel which often occur in the matrix micas.

The average and range of compositions of nine selected megacrysts are shown in Table 1, together with the averages of analyses for primary and secondary micas in peridotite xenoliths in kimberlite (ref 1 and new data) and analyses of micas from four glimmerite nodules in kimberlite (three from the Bultfontein Mine, one from the Wesselson Mine). All the analyses were made by electron microprobe techniques, of which details will be given elsewhere. Nineteen megacrysts were analysed and checked for homogeneity at five or more points, the nine selected megacrysts were homogeneous, or nearly so, whereas the others showed variations of 5% or more in Fe. Inclusion of the other ten megacrysts does not affect the conclusions.

In Fig 1, we plot TiO_2 against Cr_2O_3 for all our megacrysts and new data on micas from four peridotites, together with comparative data for ten peridotite micas given by Carswell¹. Carswell had distinguished between primary and secondary micas in peridotites by virtue of lower TiO_2 , Cr_2O_3 , Al_2O_3 , MgO and Na_2O , but higher SiO_2 in the primary micas. Our data for primary micas from peridotite fall very close to a field drawn from Carswell's analyses, whereas those for secondary micas extend towards higher TiO_2 but maintain the high Cr_2O_3 content. The same two oxides are shown for micas from the four glimmerite nodules. The lines AA' and

1, Range and mean of nine megacrysts from South African kimberlites (Hololo, Dutoitspan, Wesselton, Star, Monastery, Roberts Victor, Klipfontein, Weltvreden) selected from 19 megacrysts on the basis of chemical homogeneity

2, 3, 4, 5, Glimmerites from Wesselton (No 1083-2), Bultfontein (No 1158, with ilmenite), Bultfontein (No 1159, with amphibole and clinopyroxene), Bultfontein (No 1160, with amphibole and rutile)

6, Mean of two primary micas in ilherzolite xenolith 1141 from Bultfontein and spinel ilherzolite xenolith from De Beers 1197

7, Mean of two secondary micas in chromite harzburgite (1126, Jagersfontein) and amphibole harzburgite (1368, Monastery)

8, 9, Means of five primary and five secondary micas, respectively, from garnet ilherzolite xenoliths in South African kimberlites (from Carswell¹)

BB' at Cr₂O₃ = 0.5 and 1.1 wt % are tentatively chosen to separate the primary and secondary peridotite micas from each other and from the glimmerite micas. For the megacrysts, several features emerge

(i) None of the megacrysts falls within the range of secondary peridotite micas

(ii) Four of our megacrysts fall within, or very close to, the field or primary ilherzolite micas, and hence might be interpreted as being derived by fragmentation of peridotites containing primary micas

Fig 1 TiO₂ against Cr₂O₃ for micas. The primary and secondary micas from peridotite xenoliths in South African kimberlites, as selected by Carswell¹, are ringed by solid lines. New data for peridotite xenoliths are keyed by numbers that refer to analyses in Table 1. New data for glimmerite micas are ringed by a broken line and keyed to Table 1. All other specimens are megacrysts in kimberlite of which the average and range are listed in Table 1.

(iii) Three of the megacrysts have similar Cr₂O₃ contents to the primary peridotite micas but higher TiO₂ values, perhaps the field for peridotite micas extends to these higher values of TiO₂, or perhaps TiO₂ was introduced from the host kimberlite

(iv) Most megacrysts contain less than 0.5% Cr₂O₃, which serves to distinguish these megacrysts from the peridotitic micas and the megacrysts with peridotitic affinities. In addition, the TiO₂ tends to be higher

(v) Two of the four glimmerite micas fall directly within the group of 'non-peridotite' megacrysts whereas the other two, although having a higher TiO₂ content than the non-peridotite megacrysts, resemble them in their low Cr₂O₃

values. Here there is the indication of an affinity between the non-peridotite megacrysts and the glimmerites, suggesting that either the megacrysts result from disruption of glimmerite or the glimmerites are accumulations of non-peridotite micas

A further chemical distinction can be made between the peridotite micas and most of our megacrysts. In Fig 2, where Cr₂O₃ is plotted against FeO for the same micas, it can be seen that, in addition to the earlier Cr₂O₃ distinction, there are differences in the total FeO contents. Whereas all the primary ilherzolite micas (and possible 'peridotitic' megacrysts) contain <3.7% FeO, only three of the megacrysts with low Cr₂O₃ contain <3.7% FeO. The other ten non-peridotite megacrysts have a wide range of higher FeO values from 4.04 to 7.62 wt % FeO. The glimmerite micas also have considerably higher FeO values than the peridotite micas

In these chemical features (relatively high FeO and TiO₂, and lower Cr₂O₃) that distinguish them from the peridotitic micas, the non-peridotite megacrysts resemble other megacrysts (often referred to as 'discrete nodules') of pyrope garnet, diopside and olivine found in kimberlite; these are distinct from the broadly similar phases in peridotites in the upper mantle because of their large size, their relatively high FeO and TiO₂ content, and their comparatively low amounts of Cr₂O₃ (refs 2-4). In addition our suggestion that the glimmerites may be accumulations of non-peridotite megacrysts and thereby linked in with the overall megacryst suite, is strengthened by the fact that diopside occurring as a minor phase in one of the glimmerites (BD1159, Bultfontein Mine) is a high FeO/low Cr₂O₃ variety that chemically resembles the diopside 'discrete nodules' occurring in kimberlite. The

Fig 2 FeO against Cr₂O₃ for micas. Ornament as in Fig 1

megacryst suite as a whole, in its relatively high FeO and TiO₂, but lower Cr₂O₃, contents seems to be strongly tied in with the kimberlite event when FeO and TiO₂ (together with many other minor and trace elements) were strongly concentrated relative to presumed parental peridotite⁵

In summary, two distinctive groups of phlogopite megacrysts have been recognised, namely chromium-rich peridotite-derived micas and titanium-rich kimberlite megacrysts. The distinction between the two is important when using the megacrysts for dating purposes as an analysis of a sample consisting of indiscriminated megacrysts would yield a meaningless, hybrid age. In addition, in models for the genesis of kimberlite by fractionation of high pressure phases (the discrete nodule suite) from a primitive ultrabasic parent magma, phlogopite fractionation will have to be taken into account, in addition to that of garnet, pyroxene and olivine.

Flow separation in meander bends

It is generally assumed that downstream flow through meander bends is helicoidal and is accompanied by a transverse, bottom flow component directed towards the inner bank¹⁻³. Thus particles of sediment on a point bar are transported at some angle inwards from the generalised local downstream flow vector^{4,5}. As pointed out by Bagnold², however, "a stage

must be reached at which the flow along the inner boundary becomes unstable and breaks away from the boundary, leaving an intervening space occupied by a zone of unstable and confused motion". The experimental results of Leopold *et al.*⁶ leave no doubt that this phenomenon of flow separation (Fig. 1) can be a highly important feature in river hydraulics. Since 1960, however, no workers have extended these initial experimental ideas into field situations. Existing models of sedimentation and erosion in sinuous channels^{4,5} ignore any possible effects of flow separation. Here we draw attention to examples of flow separation in natural meander bends and attempt to define an empirical criterion for predicting the onset of separation.

Flow separation in meander bends is best expressed as a function of bend tightness and Froude number⁶. Bend tightness is most usefully defined as the dimensionless ratio between meander radius (R_m) and flow width (w) (Fig. 2). This ratio should represent a legitimate scaling factor for both small and large channels since both width and radius bear approximately linear relationships to channel magnitude expressed as meander wavelength⁷. Use of the Froude number (dimensionless) as the other variable allows results from a wide range of channels to be compared.

Our results for the occurrence of flow separation in natural meanders were obtained from intertidal meandering channels in the Solway Firth, Scotland⁸. These are cut into interlaminated muds and silts, and are suspended-load channels according to the terminology of Schumm⁹. Four meander bends were studied, observations and measurements (23 in all) being made during several ebb tides. A wide range of R_m/w Fr values were obtained (see Fig. 2). The results indicate that flow separation is possible in a range of meanders at quite modest Froude numbers (0.27–0.42). Reaches showing flow separation are well separated from those which do not. The discriminant curve drawn indicates that flow separation is a steeply decreasing function of Froude number as the meander bend becomes less tight. The discriminant curve has been extrapolated to the left in Fig. 2 to take in the experimental and field data of Rozovski³, where no flow separation was noted, and the field data of Taylor *et al.*¹⁰, where flow separation was observed. In the latter case the Froude number for the flow was quoted only as less than 0.1. Figure 3 shows a replot of experimental

Fig. 1 Sketch to show the main characteristics of separated flows in meander bends

Fig. 2 Dimensionless graph to show the occurrence of flow separation in natural channels. Data points 1 and 2 refer respectively to experimental and field results (R. Desna) showing no flow separation (ref. 3). Data point 3 refers to the River Barwon (ref. 10) where flow separation was observed but where the Froude number is given only as less than 0.1. ●, No flow separation; ▲, flow separation; R_m , meander radius; w , flow width; U , mean velocity; D , flow depth.

data for the onset of spill resistance⁶ as the flow in meander bends becomes locally critical. This plots sensibly to the right of the discriminant curve of Fig. 2 and follows the same general trend. Comparison of field and experimental data confirms that flow separation in meanders is not confined to flows which exceed the spill resistance threshold.

The effects of flow separation in our study reaches were: (1) a decrease in the effective width downstream and opposite the separation point of up to 50%, thus greatly increasing the local velocity and hence the erosion rate for the outer bank (Fig. 1); (2) rapid deposition of suspended silt in the inner

Fig. 3 Dimensionless graph showing the discriminant curve of Fig. 2 (---; depth range = 50–350 mm, Solway Firth) together with curves marking the onset of spill resistance in experimental channels⁶. ▲, Data of ref. 6 for onset of spill resistance in experimental meandering channels (flow depth = 27 mm); ▲, same for channels 20 mm deep. Note the depth effect in the latter curves. Also shown are Allen's model channels⁴ used in his theoretical study of deposition in meander bends (■ (A–F)). We predict that channels A, B, C and E should show flow separation at bankfull discharges.

separation zone (Fig. 1) and development of upstream-facing current ripple bedforms. The boundary between the main downstream channel flow and the more sluggish fluid in the separation zone periodically deforms into spiral vortices. These decay as the separation zone merges back into the general downstream flow at the meander inflection point. The decay and inward movement of eddies associated with these vortices is the cause of the high deposition rates of suspended sediments noted above (up to 20 mm in one ebb/flood cycle).

Our results suggest that flow separation is to be expected in many natural rivers. Of particular interest is the role of the separation eddy in local upstream sediment transport and bedform migration. Such features have been but rarely noted. Their development in the Rivers Mississippi¹¹ and Barwon¹⁰ suggests that flow separation is not restricted to small channels and that the plot in Fig. 2 may be sufficiently valid to warrant general application. Further measurements in natural rivers are needed to confirm and extend the present work.

A further consequence of flow separation is that theoretical models of deposition on point bars that assume a bar-hugging downstream flow cannot be valid for all natural channels. Allen's model channels⁴ are plotted in Fig. 3 and comparisons with our results suggest that several of these should show flow separation during bankfull discharges. This effect might give rise to suites of bedforms and gradations in grain size not predicted by the theoretical analysis.

Experimental observation of Abraham force in a dielectric

MINKOWSKI's momentum-energy tensor¹ for material media was severely criticised by Einstein and Laub². The density force on matter according to these authors is:

$$\mathbf{f}_M = \rho \mathbf{E} + \rho \mathbf{v} \times \mu_0 \mathbf{H} + (\mathbf{P} \cdot \nabla) \mathbf{E} + (\mathbf{M} \cdot \nabla) \mathbf{H} - \frac{1}{2} \nabla (\mathbf{E} \cdot \mathbf{P} + \mathbf{H} \cdot \mathbf{M})$$

$$+ \mu_0 \frac{\partial \mathbf{P}}{\partial t} \times \mathbf{H} + \epsilon_0 \mathbf{E} \times \frac{\partial \mathbf{M}}{\partial t} - \frac{\partial}{\partial t} (\mathbf{D} \times \mathbf{B} - (1/c^2) \mathbf{E} \times \mathbf{H}) \quad (1)$$

$$\mathbf{f}_{E-L} = \rho \mathbf{E} + \rho \mathbf{v} \times \mu_0 \mathbf{H} + (\mathbf{P} \cdot \nabla) \mathbf{E} + (\mathbf{M} \cdot \nabla) \mathbf{H}$$

$$+ \mu_0 \frac{\partial \mathbf{P}}{\partial t} \times \mathbf{H} + \epsilon_0 \mathbf{E} \times \frac{\partial \mathbf{M}}{\partial t} \quad (2)$$

with $\mathbf{D} = \epsilon_0 \mathbf{E} + \mathbf{P}$, $\mathbf{B} = \mu_0 \mathbf{H} + \mathbf{M}$ and using SI units.

Abraham³ assumes a different density force which agrees with equation (2) in the terms depending on time derivatives.

For an isotropic and homogeneous material the relationship between Abraham and Minkowski density forces is⁴:

$$\mathbf{f}_A = \mathbf{f}_M + [(\epsilon_r \mu_r - 1)/c^2] \partial(\mathbf{E} \times \mathbf{H})/\partial t$$

the last term (the 'Abraham term') has been the subject of a long and difficult theoretical controversy. Although some experiments, such as those described in refs 5 and 6, seemed at first glance to favour Minkowski's point of view, they could equally well be explained by Abraham's tensor⁷.

A direct experiment has been suggested by Marx and Gyorgyi⁸ to verify the reality of the Abraham term. This has never been carried out, to our knowledge, because of the smallness of the expected effect. Pauli⁹, Møller⁹ and others seemed to be pessimistic regarding the possibility of deciding this annoying theoretical discrepancy by a direct experimental check. But our experiment, a refined version of the one suggested by Marx and Gyorgyi, has conclusively proved that the Abraham term not only exists but is measurable with a reasonable degree of accuracy. This finally resolves the old question in favour of Einstein-Laub and Abraham.

The principle of the experiment was as follows: a disk of barium titanate, of dielectric constant near to 4,000, had a small central hole and the edges coated with aluminium to act as a cylindrical condenser. A long tungsten fibre, 0.2 mm in diameter, held the ceramic disk as a torsional pendulum between the two poles of an electromagnet having a vertical uniform magnetic field of about 10 kgauss in the 3.5-cm air gap in which the disk was suspended. The outer edge of the disk was grounded to the bottom pole of the magnet with a vertical very thin strip of gold which did not sensibly alter the mechanical behaviour of the torsional pendulum nor add any measurable Lorentz force. A focused laser provided a 10-m optical arm to amplify the damped oscillations of the torsional pendulum.

In order to synchronise the applied voltage to the torsional oscillations a signal was obtained from a photo-resistor activated each time the light beam crossed the scale. A sinusoidal voltage was generated with peak value 150 V. This voltage was then applied across the dielectric and could be set in phase or in antiphase with the torsional oscillations.

The mechanical force acting on the disk, according to Abraham, would be given by $(\partial \mathbf{P}/\partial t) \times \mu_0 \mathbf{H}$ where \mathbf{P} is the polarisation of the dielectric. In our case the corresponding torque amplitude was about 2.5×10^{-10} N m. According to Minkowski there would be no torque.

The first problem to be overcome in carrying out the experiment was the reduction of noise, occasioned by vibration in the laboratory, to an acceptable level. This was accomplished by mounting the entire apparatus on a platform weighing about 1 ton which was suspended from the roof by a cable which included a damping element in the form of an automobile tyre. The light beam was broken into four paths by mirrors and the final scale was mounted near the apparatus on the same platform. The periodicity of the support system was about 20 s whereas it was only 2.9 s for the torsional pendulum, so there was no noticeable coupling. The most annoying difficulty was that electrostatic forces appeared between static charges forming on the conductors feeding the condenser and their images in the poles of the electromagnet. These were reduced to an acceptable level by allowing an adequate gap between the ceramic and the poles and reducing the alternating applied voltage. With 300 V (peak-to-peak) the total system noise (electrical plus mechanical) gave a deflection of the light spot on the scale of about 1 cm.

The expected stationary amplitude attributable to the Abraham term is about 3.7 cm. In fact, after 1 h of transient, we measured a steady amplitude of (4 ± 0.5) cm. The effect has been checked by reversing the magnetic field and, in other cases, by changing from phase to antiphase the application of the alternating voltage. The observed changes in the transient oscillation agreed, within the error limits, with the predicted values of Abraham's density force.

In order to obtain a more accurate measurement of the Abraham term we are refining the experiment, adding a vacuum system which should reduce damping by about a factor of 4.

Thermal effects in the necking of thermoplastics

THE new technique of thermovision has been used to study deformation and fracture processes in polymers^{1,2}. This technique provides a thermal image of the polymer surface, taken by means of natural infrared radiation in the wavelength range 2 to 6 μm . The method also allows an estimate to be made of the surface temperature of a polymer, although the value obtained may sometimes be low because of transparency in the polymer films.

Following our first experiments¹, we recently made a film to demonstrate the formation of hot areas during polymer deformation processes. During this work we observed an apparently novel feature of the normal necking process, using rigid poly(vinyl chloride) and polycarbonate plastics. At a moderately high strain rate (10.0 h^{-1}) we found that with PVC only one end of the necked region of the polymer was heated, that is, all the 'cold' drawing was taking place at one point (Fig. 1), whereas with polycarbonate drawing was distributed between the two ends of the necked region (Fig. 2).

Fig. 1 Thermovision photograph of the necking of PVC. Estimated minimum temperature rise was 9°C .

Table 1 Temperature and strain rate sensitivity of the drawing stress σ_D of PVC and polycarbonate plastics

	PVC	Polycarbonate
$\frac{d\sigma_D}{dT}$	(Temperature sensitivity) $-0.71 \text{ MN m}^{-2} \text{ per } ^\circ\text{C}$	$-0.25 \text{ MN m}^{-2} \text{ per } ^\circ\text{C}$
$\frac{d\sigma_D}{d(\ln \dot{\epsilon})}$	(Strain rate sensitivity) 1.5 MN m^{-2}	1.0 MN m^{-2}
Glass transition temperature	67°C	160°C

We suggest the following explanation of this difference in behaviour. With PVC the fall in stress caused by an increase in temperature at the neck greatly exceeds that which would be achieved by the halving of the strain rate which occurs when yielding takes place at each end of the necked region. Thus the reduction in heat losses because of the higher strain rate when

**Fig. 2** Thermovision photograph of the necking of polycarbonate. Estimated minimum temperature rise was 6°C .

straining occurs only at one end dominates the strain rate effect and the plastic strain process becomes localised at one end of the test piece. This explanation is supported by the data given in Table 1; the temperature sensitivity of the drawing stress for PVC is greater than for polycarbonate, whereas the strain rate sensitivity (at low strain rates) is not very different for the two polymers. The increased temperature sensitivity of PVC is, of course, related to its lower glass transition temperature as shown in Table 1.

Hydrodynamic pressure under a piston ring

CASTLEMAN postulated¹ that the lubrication of piston rings might be hydrodynamic. Recently it has become possible to measure the oil film thickness directly, using a capacitance transducer². Oil film thicknesses of the order of $1 \mu\text{m}$ have been measured in a small diesel engine; theory predicts thicknesses of

**Fig. 1** The pressure gauge in the liner wall.

the order of $10 \mu\text{m}$. To investigate this discrepancy it was decided to measure the pressure in the oil film, since this provides an independent check on the theory.

A miniature pressure transducer was designed capable of operating in the conditions of a working engine. Essentially the transducer consisted of a cone-shaped plunger which transmitted the pressure from the cylinder face to a piezoelectric crystal (Fig. 1). The plunger was sealed at the front face of the cylinder by a flexible cement, the effective resolving power of the gauge being 0.025 cm . By mounting a capacitance transducer alongside the pressure gauge it was possible to obtain a synchronised oscilloscope display of pressure and film thickness.

**Fig. 2** Output from capacitance and pressure gauge on exhaust stroke.

Experiments have been carried out on a Petter AV1 diesel engine made available by Mr R. P. Langston of the Admiralty Oil Laboratory, Cobham. Figure 2 shows a result taken at 950 r.p.m. on the exhaust stroke. The upper trace is from the capacitance transducer; the presence of the rings is indicated by the out-of-balance signal. The lower trace is from the pressure gauge, the signal level being directly proportional to pressure. The first ring seen, on the left-hand side of the photograph, is the nominally parallel faced compression ring (running-in has

modified the profile to a slight taper), this is followed by two downward scraping taper-faced rings and finally a stepped-scraper ring. These traces show that the pressure distribution does not extend over the whole of the converging gap between the piston ring and the cylinder liner. This is contrary to the assumption of the elementary theory. The rings can be said to be operating in conditions of starved lubrication, presumably caused by the working of the ring-pack.

Details of the method of calibration together with a full account of the effect of engine conditions will be given elsewhere. Although the results do not conform completely with the details of simple theory, it is believed to be the first time that the pressures postulated by Castleman¹ have been observed directly.

Field-desorption microscopy and the atom probe

WE have found unexpected and finely detailed field-desorption patterns, which demonstrate that the yields of metal ions from the surfaces of specimens in the field-ion atom probe are a function of the crystallography and sometimes also of the materials.

The field-ion atom probe¹, in which a field-ion microscope is combined with a time-of-flight mass spectrometer, has been shown to be a useful instrument for the chemical analysis on an atomic scale of metals and especially of alloys²⁻⁴. In an analysis, the field-ion specimen is manipulated to place an image feature over the entrance aperture of the mass spectrometer, which typically subtends only a few image points; a high voltage pulse is then applied to the specimen to desorb

a small amount of material. Ions desorbed from the selected feature pass through the aperture and their mass-to-charge ratios may be deduced from their flight times to a detector. The atomic resolution of the field-ion microscope in principle allows the feature to be chemically analysed atom by atom.

In practice, however, the ion yield is found to be a sensitive function of the position of the selected feature on the specimen surface. Brenner and McKinney⁵ have described systematic 'aiming errors' due to displacements of the trajectories of the field-evaporated metal ions from those of the ions of the image gas.

We have used a simple field-desorption microscope⁶ to investigate these phenomena directly. In this instrument an image is formed of the arrival positions of field-evaporated metal ions at the screen of a conventional field-ion microscope fitted with a micro-channel-plate image intensifier⁷. The image may be recorded directly using large aperture optics and a fast film (Kodak Tri-X or 2475 recording film), with up to 1,550 V applied to the channel plate; under these conditions the detection efficiency for single ions was estimated to be 20 to 50%. Alternatively, the channel plate gain and the lens apertures could be reduced to allow the image to be formed by the evaporation of many layers of the surface without saturation of the film. Proximity focused channel-plate intensifiers were found to be more suitable at very fast evaporation rates than magnetically focused intensifiers, which suffer from space-charge defocusing at the very high currents involved; this is likely also to apply to external image intensifiers.

When fractions of a monolayer of a tungsten surface were pulse evaporated to form the desorption image, micrographs similar to those presented by Walko⁸ and Panitz^{9,10} were obtained. Direct comparison of the field-ion and field-desorption images from the same surface demonstrates the general validity of Brenner and McKinney's conclusions concerning the directions of aiming errors, and allows their accurate measurement for different parts of the specimen surface.

When many planes of tungsten or other metal surfaces were evaporated to form the image, at reduced intensifier gain, very striking and unexpected intensity distributions were

Fig. 1 Field-desorption micrographs at 78 K. *a*, Tungsten, <110> centred, evaporated by multiple 15-ns pulses; inset continuous evaporation, showing ring structure, zone decoration and radial bright lines towards the {211} planes. *b*, Rhodium, a typical f.c.c. pattern. *c*, Nickel. *d*, Aluminium in ultra-high vacuum. The f.c.c. patterns are all continuous evaporations and <111> centred.

obtained (Fig. 1 a-d). These became more well defined as more of the surface was evaporated, and were reproducible. Only minor variations were introduced by using evaporation pulses of 15 ns, 80 μ s or 500 μ s, or rapid continuous evaporation, or by superimposing many 15-ns pulses. As these patterns have been observed reproducibly under extremely diverse conditions using both proximity and magnetically focused image intensifiers, the possibility of instrumental artefacts (such as channel plate saturation¹¹) may be discounted. The patterns for the more refractory metals (such as W, Ir, Re, Mo) were largely independent of vacuum conditions in the range 2×10^{-10} torr to 5×10^{-8} torr at 78 K. In contrast, the pattern from the non-refractory aluminium was severely modified by as little as 5×10^{-9} torr of hydrogen.

The desorption patterns from b.c.c. metals (such as W, Ta, Mo, Fe) are as varied in character as the corresponding field-ion patterns. Those of the f.c.c. metals (Ir, Au, Rh, Pd), with the notable exception of aluminium, are all very similar, showing bright and dark line contrast with a faint background pattern of dark lines. A similar desorption pattern has been reported recently by Muller and Tsong¹⁰. Nickel is similar in the central region of a (111)-centred specimen, but shows a more complex pattern towards the edges, perhaps due to local mechanical deformation. Aluminium alone shows only dark lines in the desorption image. Dark centres to major planes are commonly seen, as are concentric ring structures centred on such planes (for example, {110} tungsten, {111} for Rh and Al); these structures persist even when hundreds of planes are evaporated to form the image.

We believe that the origins of these desorption patterns lie in short-range migration of atoms¹², induced by polarisation forces in the high electric field, along specific surface directions during the evaporation process; we do not think that differences in local magnification associated with differences in local curvature can alone lead to the observed detailed contrast, and in particular to the bright-line contrast, as originally suggested by Muller for platinum¹⁰. Coulomb repulsion between simultaneously evaporating ions is likely to contribute to the dark centres of major planes, which are more pronounced at high evaporation rates. Whatever the full explanation, we conclude that field-desorption microscopy will lead to a better understanding of the field-evaporation process and is an essential complement to atom-probe field-ion microscopy. This is particularly so for the analysis of very small precipitates and for analysis of segregants at grain boundaries, where we have observed both bright and dark contrast in the desorption micrograph. Provided that such effects are recognised, the atom probe remains the only instrument capable of accurate chemical analysis on an ultra-fine scale.

We thank Drs A. J. W. Moore and J. A. Spink for comments, and the Science Research Council for grants.

Lead in urban street dust

LEAD pollution and its effects on health are matters of general concern^{1,2}. The potential danger to children is now receiving particular attention. Lead in various inorganic forms may be inhaled or ingested, and various sources of ingested lead (for example food, tapwater, paint) are recognised, and tolerable limits have been established. Recently, it was claimed² that for children in urban surroundings the dust of streets and playgrounds is a potentially significant source of lead, and that the lead in such dust can be over 1,000 p.p.m. (0.1%). This is a source of lead which is not immediately controllable, but we consider that its importance as a component of the lead intake of urban children has not been sufficiently assessed.

This investigation has two simple objectives: to determine the lead content of the dust and dirt likely to be encountered by children as a normal part of their environment in Greater Manchester, and to assess the importance of the dust as a component of the lead intake of urban children. Our results show an average lead concentration of 970 p.p.m., with little significant variation either with type of locality (main road, side street, playground, and so on), or with position within the urban area. Samples from nearby rural areas had average concentrations of 85 p.p.m. By comparison, typical values¹ for rural soils in Britain fall in the range 50 to 100 p.p.m., whereas the lead content of 'uncontaminated' soils is ~ 10 p.p.m. Our results for urban dust are similar to those obtained in other cities, for the few studies of which we are aware. In Birmingham, most values (R. Stephens, personal communication) were between 1,000 and 2,500 p.p.m. (average $\sim 1,700$ p.p.m.), the average for Rio de Janeiro³ was 700 p.p.m., and the averages for 77 cities in the USA (ref. 4) were between 1,500 and 2,400 p.p.m.

The 350 urban samples collected were of street dust, surface dirt or soil, from pavements, roadside gutters, children's playgrounds in parks, primary school playgrounds, gardens and waste land, over an area within ~ 10 km of the centre of Manchester, during the period December 1972 to March 1973. (In the south-east, the area sampled extended 15 km.) Twenty-five similar samples were also collected from a children's playground and a park in a rural area ~ 1 km outside the built-up zone, to the south-east of the area and ~ 15 km from the centre of Manchester. The samples were dried at 120° C and homogenised by grinding. Portions (~ 1 g) were boiled with 2 M nitric acid for 30 min. The lead content was determined by atomic absorption spectrophotometry and, for a randomly selected 10%

Fig. 1 Numerical distribution of lead concentration. Numbers above full arrows are percentages of samples below lead concentrations indicated.

Table 1 Data subdivided according to type of locality (A–D, urban; E, rural)

Type	Definition	No. of samples	Mean Pb concentration (p.p.m.)	Standard deviation
A	Major roads/streets; moderate/heavy traffic 0800–2000	180	1,001	40
B	Minor roads/streets; light/moderate traffic 0800–2000	68	888	57
C	Streets with very light traffic only, and 'play streets'	53	933	186
D	School playgrounds; childrens' play areas in parks, gardens, waste land	49	1,014	206
E	Rural locations; childrens' playground and a 'country park'	25	85	40
A–D	All urban areas	350	970	46

of the samples, by polarography. Agreement between the two methods was always better than $\pm 3\%$.

The average lead concentration in the urban samples was 970 p.p.m. (standard deviation 46); the numerical distribution is shown in Fig. 1. The highest value encountered was 10,200 p.p.m. and the lowest 90 p.p.m. But the higher values were unusual; only 10% of the samples had lead concentrations above 1,500 p.p.m. and only 5% above 2,000 p.p.m. The median value was 860 p.p.m. and the middle 50% of samples ranged from 550 to 1,200 p.p.m.

The urban samples were subdivided into four divisions, according to the type of locality (A–D, Table 1). There was no significant difference between the average lead concentrations in any of these subdivisions. The average lead concentration in the samples from the rural areas was 85 p.p.m., the type of locality being comparable with subdivision D.

We examined the geographical dependence of our analytical data in three ways. First, we subdivided the city into quadrants, and calculated the average lead concentrations for each quadrant. There was no significant difference between quadrants (Table 2).

In the second method we examined the data for a possible relationship between lead concentration and distance from the centre of the urban area. The distance of each sampling point from the centre (St Peter's Square) was calculated and the distances subdivided into 1-km intervals. The average lead concentration for the samples in each interval was calculated,

Fig. 2 Radial distribution of lead concentrations from the centre of Manchester. Quadrants NE, - - - -; SE, ---; SW,; NW, — · — · —; all, ———.

for each quadrant separately and for all samples. The resultant radial distributions (Fig. 2) fluctuated between about 600 and 1,400 p.p.m., with no significant general rise or fall with distance except for a sharp reduction at the distance corresponding to the edge of the urban area.

Third, we attempted to produce a density map of the area. For each 1-km square (National Grid), we compared the average value of the lead concentrations with the map of Greater Manchester. No general pattern emerged, and there was no apparent correlation with major roads or local centres of commercial and/or industrial activity.

It seems reasonable to assume that the bulk of the lead in the urban dust was at some time airborne. The principal sources of airborne lead¹ are probably vehicle emissions (> 90%), smoke from coal and refuse burning, and emissions from various metallurgical and industrial processes. The geographical distribution of lead contamination of the dust seems to support the view that much of the lead is airborne for periods of up to several weeks, and presumably more or less complete mixing of lead from the various sources must occur. As a result, a reasonably uniform dispersal takes place.

Table 2 Data subdivided according to quadrant of city (urban samples only)

Quadrant	No. of samples	Mean Pb concentration (p.p.m.)	Standard deviation
North-east (NE)	43	988	59
South-east (SE)	165	888	58
South-west (SW)	85	983	90
North-west (NW)	57	1,180	181

The importance of urban dust as a direct source of lead for humans must be assessed in relation to the intake from other sources, and the "provisional tolerable intake" recommended by the WHO. Considering only food, water and air as sources, ingested lead is estimated normally to contribute over 90% of the daily lead intake². Although less efficiently absorbed than inhaled lead⁶, ingested lead is by far the more important source^{5,7}. The recent *Survey of Lead in Food* (United Kingdom)⁸ estimates that for the average adult the intake of lead from food is $\sim 200 \mu\text{g d}^{-1}$, with a further $20 \mu\text{g}$ from liquids. A figure was not derived for children, but on the basis of the recommended caloric intake of food⁹, children (averaged over the ages 1 to 9) would reach 75% of the adult figure, $165 \mu\text{g d}^{-1}$.

A "tolerable intake" of ingested lead for adults was recently established (ref. 9 page 19, and ref. 10) at 3 mg per week (0.05 mg per kg body weight), equivalent to an average daily rate of $430 \mu\text{g}$, infants and children being specifically excluded. But the average weight of children (age 1–9) is $\sim 30\%$ of the adult average⁹, and on a weight ratio a tolerable daily intake would be $130 \mu\text{g}$. If children are more at risk than adults¹¹, this figure should presumably be reduced, and in any case will depend on age.

We conclude, therefore, that although adults on average ingest in food and drink only $\sim 50\%$ of their "tolerable intake", children ingest an amount close to or even above their tolerable level.

For adults, urban dust seems unlikely to contribute a significant quantity of lead to the daily intake. But for children even small quantities of dust would be significant. It seems to us that children who play in areas containing this type of dust are likely to ingest some of it, perhaps by casually eating sweets while playing in the street. We are not aware of any large scale determination of the amount of dust and dirt which is typically ingested by children. We have, however, made a small number of direct measurements and find that a child can transfer from 5–50 mg of dirt from his hands (dirty from 30 min of activity in a normal urban playground) to a typical 'sticky sweet' (5 g). An ingestion of $100 \mu\text{g}$ of lead (contained in 100 mg of average

dust) could result from the consumption, under these conditions, of from 2 to 20 sweets, which probably encompasses children's normal sweet-eating habits. Also, it is possible to envisage lead ingestions much greater than this—20 badly contaminated sweets could contain 1,000 μg of lead.

We conclude that children in urban surroundings, who may already be ingesting in food and drink an amount of lead approaching a tolerable limit, may considerably increase their daily lead intake by the accidental ingestion of dirt and dust from their surroundings in the course of their normal everyday activity. This source of lead does not at present seem to be recognised as a potential hazard. Thus, although upper limits for lead in food (generally 2 p.p.m.) or lead in paint for children's toys (0.5%) are recognised as being desirable, no tolerable upper limit for lead in urban dust has been suggested. We consider that this is an urgent and important problem.

We thank the many students of the University of Manchester who collected samples, Maureen Blundell, Gwendoline Fowden and Susan Peak of our Microanalytical Section for technical assistance, and the Science Research Council for financial support (to M. S. R.).

Lead levels in blood of residents near the M6–A38(M) interchange, Birmingham

LEAD levels in blood are generally found to be higher in city dwellers than in those living in the country^{1–6}. This difference has been linked to the increased background levels of lead, which result to a large extent from the emission of lead in motor car exhaust gases. In Birmingham, the opening of the M6–A38(M) interchange provided an opportunity to test this hypothesis by studying the effect of an increase in traffic density on the concentration of lead in the blood of those living close to the interchange.

Capillary blood samples were taken from volunteers living within 800 m of the interchange immediately before its opening in May 1972. Second blood samples were collected between October 1972 and February 1973, and a third collection was made in October 1973. Although a large number of samples were taken, only a relatively small number of persons contributed blood to each of the three series and it is the results from these people which are discussed here. All the estimations of blood lead were carried out at the same laboratory, using an atomic absorption technique. Because of some difficulties with skin contamination experienced during the collection of the first series of blood samples, venous blood was taken for the second and third analyses. No control group was studied.

Two groups were followed through the three series, the first consisting of 41 males and the second of 58 females. The mean

blood lead concentrations in the three series were, for the male group, 14.41, 18.95 and 23.73 μg per 100 ml and for the female group, 10.93, 14.93 and 19.21 μg per 100 ml. For both groups the differences between the first and second, second and third and first and third means are statistically significant as judged by paired *t* test analysis (Table 1).

Table 1 Statistical analysis of mean lead concentrations in the blood of two groups of residents living near the M6–A38(M) interchange

		Series		
		1:2	2:3	1:3
Males	Mean difference	4.54	4.78	9.32
	Standard error	1.72	1.55	1.46
	<i>P</i>	<0.05	<0.01	<0.001
Females	Mean difference	4.00	4.28	8.28
	Standard error	0.94	0.87	0.95
	<i>P</i>	<0.001	<0.001	<0.001

The M6 opened on May 24, 1972. In April 1972, 361,040 cars a week used the road later incorporated into the interchange. By March 1973, 748,639 cars a week were using the whole interchange and by March 1974 the weekly figure was 900,451.

When interpreting these results due consideration must be given to the fact that the method of blood sampling was changed after the first series and that the samples in each of the three series were not all taken at the same time of year. During the course of the study, however, capillary and venous samples were taken on the same occasion from a total of 96 different individuals in the main study (47 males and 49 females) and it was found that the blood lead concentration in the capillary samples tended to be higher than in the venous samples. Thus any bias introduced into the study by changing the sampling method would seem to be against showing a rise in the blood lead concentration. Similarly, it has been shown that the blood lead concentration is higher in March–July than during the rest of the year⁷ so that in taking the second and third samples during October–February, and not in May when the first sample was collected, a bias is again introduced which is against showing an upward trend. Thus, despite the defects in experimental design which undoubtedly mar the study, the results suggest an increase in the mean blood lead concentration of the two groups of residents over a period when the volume of traffic on the motorway was increasing. The blood lead concentrations are, however, higher than might have been predicted from the atmospheric concentrations using the model of Knelson *et al.*⁸ The concentration of lead in the atmosphere in the residential areas near the motorways is approximately 1 $\mu\text{g m}^{-3}$ although values greater than this are found at sites closer to the road⁹. Knelson and Bridbord¹⁰ have suggested that continued exposure to atmospheric lead levels of the order of 1–3 $\mu\text{g m}^{-3}$ will produce increases in the blood lead concentration, and their theoretical considerations have received some support from experiments on human subjects exposed to low atmospheric lead concentrations produced under controlled conditions¹¹. In these considerations, however, the total amount of lead in the atmosphere is of less importance than its particle size. The model proposed by Knelson⁸ assumes a constant pulmonary absorption rate of 37%. Now if the lead aerosol particles around the interchange are small enough to enable the aerosol to assume the properties of a gas, then maximum lung penetration will be achieved and pulmonary absorption may well be considerably higher than 37%. A preliminary study¹², which has shown that the atmospheric lead levels inside one house near the interchange are almost identical with those outside and follow the same diurnal fluctuation, is consistent with the notion that the aerosol is, in fact, behaving as a gas.

A number of workers^{13–16} have found the mass median diameter of airborne lead particles to be of the order of 0.10–0.90 μm although electron micrographs have shown that

the lead particles may form large aggregates with other material in the atmosphere¹⁷. Whether this aggregation takes place during emission from the tail pipe or during sampling is, however, unresolved. Clearly it would be of considerable interest to have more information about the physical and chemical characteristics which might affect pulmonary absorption of the particles of lead in the atmosphere around the interchange. It should also be borne in mind that factors other than the inhalation of lead from the atmosphere might be contributing to the increase in blood lead—for example, the ingestion of lead-contaminated dust.

I thank the Environmental Services Committee of the City of Birmingham for inviting me to analyse these data.

Interactive effects of unpleasant light and unpleasant sound

IN tests of colour preference, rhesus monkeys have been found to have a strong aversion to light at the red end of the spectrum^{1,2}. No comparable reaction to colours has been described in healthy human beings although in patients who are suffering from cerebellar or spinal disorders colours may assume a new potency. Thus it has been claimed that in cerebellar patients who exhibit the so-called 'sensorimotor induction syndrome', red light not only exacerbates the motor disorder but disrupts thought processes and leads to acute subjective distress, whereas blue-green light alleviates the symptoms^{3,4}. Furthermore, Halpern and Feinmessenger⁵ found that in such patients red light, besides causing discomfort in itself, increases the sensitivity to noxious auditory stimulation: in their experiments the 'threshold of acoustic discomfort' was consistently lowered when the patients wore red filters in front of their eyes. So we have investigated in monkeys whether the aversion to red light is increased when the preference tests are conducted in the presence of unpleasant background noise.

The technique for measuring the monkey's reactions to red light was similar to that previously described². The monkey sat in a small dark chamber with a screen (40 cm × 40 cm) at the far end, on to which red or white light could be projected. The red light (Kodak Wratten filter 25) and the white light were matched in subjective brightness at 1.5 log foot lamberts. The monkey controlled the presentation of the two stimuli by pressing a button. Successive presses

on the button produced the red and the white light in strict alternation, either stimulus staying on for as long as the button was held down. Each test lasted for 400 s of total exposure, during which time the monkeys typically alternated between the two stimuli about 100 times. The relative preference for the red light was measured as the ratio of the time spent with the red light to the total time spent with either red or white light over a defined interval.

The effect of background noise on the colour preference was investigated by comparing the monkey's performance when the chamber was quiet with that when 'white noise' was played through an overhead loudspeaker during the test. The sound pressures in the 'quiet' and the 'noisy' conditions were 59 db and 80 db respectively. For comparisons to be made within a single test, each test was subdivided into eight 50-s bouts, four 'noisy' and four 'quiet' presented alternately. Each monkey was given twenty

Fig. 1 Preference for red over white light in each successive 50-s period. *a*, Monkeys 1 and 2; *b*, monkeys 3 and 4. ○, ●, 'Quiet' condition; △, ▲, 'noisy' condition. ○, △, Tests which began with noise; ●, ▲, tests which began with quiet. Each point represents the mean of the two monkeys' mean scores over ten tests.

tests, ten of which started with 'noise' and ten with 'quiet'.

Four young adult male monkeys (*Macaca mulatta*) served as subjects. Monkeys are not all equally reactive to white noise and these four were selected as being two who found noise extremely aversive and two who found it relatively tolerable. This assessment was made by running preliminary tests in which the monkeys were given the opportunity to choose between noise and quiet in a simple (noise+light)/(quiet+light) preference test⁶. In five tests, each lasting 400 s, monkeys 1 and 2 preferred the quiet condition 85% and 83% of the time, while monkeys 3 and 4 preferred it 65% and 68% of the time.

The results of the main experiment are shown in Fig. 1.

the two subgroups of monkeys being treated separately. For monkeys 1 and 2 the background noise increased the aversion to red light; for each of these monkeys the effect was significant beyond the 0.001 level (Wilcoxon test, based on the performance within each of the twenty tests). For monkeys 3 and 4, however, the noise had little if any influence; although each of these monkeys showed a marginally greater aversion to red light in the noisy condition, the effect was not significant. The implication is that background noise increases the aversion to red light if, and only if, the monkeys find the noise itself markedly aversive.

Although Halpern and Feinmesser studied the effect of red light on the aversion to noise, whereas we did the reverse in our experiment, there is an obvious parallel between the results of the two studies. The difference in experimental design is in fact more apparent than real, since, whichever way round the experiment is done, the most one can conclude is that a combination of red light and noise is unduly aversive. The experiments do not allow one to distinguish whether it is red light which increases the unpleasantness of noise or noise which increases the unpleasantness of red light; indeed, this is probably a false antithesis, the truth being that the effects of the two stimuli mutually potentiate each other.

Leaving aside the puzzle of why red light should be aversive to either monkeys or cerebellar patients, one may speculate on the broader implications of these findings. Whether it is a general rule that unpleasant stimulation in one modality potentiates the effect of unpleasant stimulation in another remains unknown; but a rule of this sort would be given a certain plausibility by Stevens' 'power law' for subjective sensation⁷. Stevens showed that when people are given electric shocks their subjective discomfort is an accelerating function of the magnitude of the physical stimulus (thus the discomfort resulting from a 40 V shock is more than twice that from a 20 V shock). Suppose, purely for illustrative purposes, that red light alone is equivalent to X units of shock, and noise alone is equivalent to Y units of shock, then the discomfort due to a combination of red light and noise may be expected to be greater than the sum of the discomfort caused by the component stimuli, since $(X+Y)^n > (X^n + Y^n)$, if the sensory exponent, n , is greater than one.

Insect hormones as tsetse abortifacients

Female tsetse flies produce only one offspring at a time, the larva being retained within the uterus where it is nurtured from the female's milk gland¹. The low reproductive potential resulting from this curious form of viviparity is a feature that can perhaps be exploited as a vulnerable link in the life cycle. My experiments show it is possible to disrupt the normal 9 d pregnancy cycle² by using insect hormones to induce abortion.

Glossina morsitans morsitans Westw. was used in the experiments reported here. Females were transferred from

mass culture to individual containers³ shortly before the first larviposition. Flies were offered a blood meal on rabbit ears 6 d a week and feeding records were kept for each fly. The hormones were applied during the second pregnancy cycle; all stages of pregnancy were represented in approximately equal proportions for each dose of hormone applied. Crystals of plant-derived ecdysterone were dissolved in 96% ethanol and diluted with distilled water to 10%; 0.5 μ l was injected into the thoracic tergum by a glass capillary. The juvenile hormone analogue isopropyl (2E,4E)-11-methoxy-3,7,11-trimethyl-2,4-dodecadienoate (ZR515) was applied to the abdomen in 5 μ l acetone. The flies were held between finger and thumb and were not anaesthetised. Each fly container was examined daily for aborted progeny.

As is seen in Table 1, the effective dose of ecdysterone required to elicit a 50% rate of abortion was between 1.0 and 10.0 μ g. Most abortions occurred during the on-going pregnancy, but a few females aborted again in the next pregnancy. A few aborted only during the next pregnancy. Observations on 45 females kept beyond the second post-injection pregnancy suggest that later pregnancies and female longevity were not affected.

Topical application of the juvenile hormone analogue (JHA) caused a 50% rate of abortion at a dose of approximately 10 μ g. As with ecdysterone, the effect was most pronounced during the on-going cycle (Table 1).

Both hormones induced abortions in the egg stage as well as in all three larval instars. Although the hormones were applied to individuals representing all stages of pregnancy,

Fig. 1 Incidence of daily feeding activity in tsetse females that aborted following either an ecdysterone injection (○) or a topical application of a juvenile hormone analogue (△). Feeding activity is expressed as the percentage of females that took a blood meal during a 15 min exposure to rabbit ears. Each curve is based on the record of 38-40 flies.

the effect was most frequently manifested in the abortion of 2nd or 3rd instar larvae. The aborted 3rd instars were not fully grown; melanisation of the cuticle² was frequently incomplete and they failed to pupariate. In the case of ecdysterone, 72% of the abortions ($n=43$) were of 3rd instars and 21% of 2nd instars. With JHA 38% of the abortions ($n=42$) were of 3rd instars and 43% were of 2nd instars. The time between hormone application and abortion was much shorter with the JHA: 42% occurred within 24 h and several aborted within 2 h. For abortions occurring during the 1st pregnancy cycle, the latent period was 2.4 ± 0.5 d (mean \pm s.e., $n=36$). In the ecdysterone-treated flies only 7% aborted within 24 h and the mean latent period was 4.2 ± 0.5 d ($n=29$).

All the abortions depressed feeding activity below normal for several days (Fig. 1). For the JHA a pronounced

Table 1 Incidence of abortion in *Glossina morsitans morsitans* Westw. resulting from injection of ecdysterone or topical application of a juvenile hormone analogue

Substance	Treatment	Dosage (μg)	No. of females	Distribution of no. of abortions during two subsequent pregnancies			Females aborting (%)
				1st cycle only	2nd cycle only	1st and 2nd cycle	
10% Ethanol	—	—	23	0	2	1	13.4
Ecdysterone	0.01	—	24	0	4	0	16.6
Ecdysterone	0.1	—	25	3	2	1	24.0
Ecdysterone	1.0	—	23	5	1	1	30.4
Ecdysterone	10.0	—	26	17	1	3	80.8
Acetone	—	—	29	2	0	0	6.9
JHA (ZR515)	0.1	—	25	1	0	1	8.0
JHA (ZR515)	1.0	—	25	3	2	0	20.0
JHA (ZR515)	10.0	—	25	9	1	2	48.0
JHA (ZR515)	50.0	—	36	13	4	4	79.0

decrease in activity occurred on the day following abortion. In spite of a decline in feeding around the time of abortion, normal larvae were produced in 10.4 ± 1.2 d (mean \pm s.e., $n=25$) after an ecdysterone-induced abortion, and in 9.2 ± 0.6 d ($n=23$) after a JHA-induced abortion.

Effective tsetse abortifacients could have several possible modes of action; first, direct influence on the act of parturition; second, 'turning off' the milk gland; third, disruption of *in utero* larval morphogenesis; or fourth, desynchronisation of the (presumed) female neuroendocrine integration of normal pregnancy².

Larvae within the uterus of a starved female can survive several days before the onset of starvation-induced abortion⁴; therefore it seems unlikely that the rapid abortion initiated by JHA could be the result of effects on the milk gland. As feeding activity in hormone-treated females (Fig. 1) was within the expected range² before abortion, malnutrition is an unlikely cause for the expulsion of immature larvae. Moreover, large milk glands were observed in numerous females that aborted.

Pharmacological agents that act on neuromuscular processes involved in parturition could also potentially act as abortifacients. Physostigmine, a reversible anticholinesterase, was moderately effective as a fast-acting abortifacient. Injection of $0.5 \mu\text{l}$ of a 0.1 mM solution of physostigmine (B.D.H. Ltd) in 10% ethanol caused 4 out of 19 females to abort within 15–30 min. All females that did not abort within 30 min successfully completed their pregnancy. Injection of a higher dosage ($0.5 \mu\text{l}$ of a 1.0 mM solution) caused 100% female mortality. Prostaglandin E_1 and prostaglandin F_2 α -tromethamine salt (Upjohn Co.) injected in dosages of $10 \mu\text{g}$ in $1 \mu\text{l}$ 10% ethanol were ineffective.

I thank Professors Jan de Wilde, Thomas R. Odhiambo, and Carroll M. Williams for their help and NIH-NIAID for a postdoctoral fellowship. Gifts of hormone analogues were kindly supplied by Zoecon Corporation and Dr Jizba from the Czechoslovak Academy of Sciences. The prostaglandins were a gift from the Upjohn Co.

Behavioural role of individual components of a multichemical attractant system in the Oriental fruit moth

In most moths, location of the female for mating is mediated by pheromones¹, which are operationally defined as attractants, although their ability to elicit upwind orientation has been demonstrated in only a few species². Intrinsically unattractive chemicals which modify this process by increasing or decreasing trap catch have been termed synergists and inhibitors¹, respectively, although their behavioural and neurophysiological roles have remained unresolved. In the Oriental fruit moth, *Grapholitha molesta* (Busck), *cis*-8-dodecenyl acetate (*c*8-12:Ac) is a primary pheromone component³ and recently the requirement for attractancy of an isomeric mixture containing about 8% *trans* (*t*8-12:Ac) was demonstrated^{4,5}. Additionally, male trap catch has been reported to be enhanced about two-fold by the simultaneous release of dodecyl alcohol (12:OH) (ref. 5). Specific behavioural functions, however, had not been ascribed to individual attractant components or combinations.

Table 1 Male behaviour within 3 m of a white sticky trap baited with attractant on a rubber septum dispenser

Stimulus	No. of males observed	Percentage captured*	Mean flight time† (s)
100 μg <i>c</i> 8-12:Ac (6.8% <i>trans</i>)	39	56	19.8
100 μg <i>c</i> 8-12:Ac (6.8% <i>trans</i>) + 300 μg 12:OH	40	93	12.5

*Compared with a 2×2 test of independence using the *G* statistic with Yates' correction: $P < 0.01$.

†Means compared with the *t* test: $P < 0.05$. Measurements were initiated on the arrival of males within 3 m of the trap's edge and terminated when males either left this area or were ensnared on a trap's lower sticky surface.

Field studies in Geneva of wild male behaviour near baited traps showed that 100 μg *c*8-12:Ac alone failed to lure males to the trap vicinity, and indeed no males were observed orienting toward the traps within about 15 m. The combination of *c*8-12:Ac with 6.8% of the *trans* isomer did lure males to the trap (Table 1), and the simultaneous release of 12:OH effected a increase in the number of males actually captured on the sticky trap surface. In terms of trap catch, the attractant 'synergist' (12:OH) seems to increase the frequency of male landing.

Detailed field analyses of the role of 12:OH were carried out using an attractant dispenser placed in the centre of a circular table top of radius 60 cm. Previous field trials had revealed that 10 μg *c*8-12:Ac with 6.8% *trans* elicited the closest mean approach to the dispensers, at doses between 1 and 3,000 μg . When various quantities of 12:OH were present along with 10 μg of the attractant, the presence of 12:OH resulted in significant increases in the frequencies of

Table 2 Behavioural effects on 12:OH when presented simultaneously with 10 µg of c8-12:Ac (6.8% *trans*) on a rubber septum dispenser

12:OH (µg)	No. of males observed	Percentage landing on table top*	Percentage fanning while walking on table top*	Percentage hair-pencil display on table top*	Mean closest approach† to attractant dispenser (cm) ± s.e.

¶ *P* < 0.01

§ *P* < 0.001

landings, wing fanning while walking, approach to the chemical stimulus and extrusion of hair-pencils⁶ at the abdominal tip (Table 2). This is the first example of a particular chemical component evoking hair-pencil display.

Although to date only c8-12:Ac has been confirmed from female *G. molesta*, this species seems to utilise a multicomponent communication system. Both c8- and t8-12:Ac are requisites for attraction but this combination seems to elicit relatively little fanning and almost no extrusion of hair-pencils close to the attractant source. The main effect of 12:OH, previously considered an attractant synergist, is apparently to elicit a repertoire of precopulatory behaviour, which is likely to increase the catch in a trap.

The finding of disparate communicative functions for chemicals thought to be attractants and modifiers has implications for control programmes based on the disruption technique, in which the pheromone permeates the atmosphere so that either the males fail to locate the females (confusion) or habituation of mating responses⁷ occurs. Successful implementation of this procedure may ultimately depend on an intimate understanding of the precise communicative role of individual pheromonal components, since manipulation of attraction alone may not obviate mating.

Coral diseases in Bermuda

WE report here diseases of reef corals that seem to be associated with bacterial infection. On reefs around Bermuda, where our field work was carried out in the summer of 1973, the most commonly affected species are the brain corals *Diploria labyrinthiformis* and *D. strigosa* (Fig. 1). We believe that this is the first unequivocal report of a coral disease and our observations suggest that diseases may be important agents of coral death. (There are some indications that others have seen diseased corals^{1,2}.)

The distribution of diseased colonies is difficult to evaluate because only 0.5–1% of the *Diploria* colonies are affected at a given time. Diseased colonies, however, occur throughout the reefs. Their distribution seems unrelated to inshore

pollution sources and to areas of greater or lesser circulation.

On the reefs the *Diploria* disease appears as a dark brown line separating a dead from a live portion of a colony. The coral is apparently healthy, with all its zooxanthellae up to the disease line (Fig. 2), while on the other side of the line no tissue remains. The disease consumes tissue at a rate of a few centimetres per month. The exposed corallum behind the line of infection is soon covered with filamentous algae and diatoms.

Fig. 1 Infected colony of the brain coral *Diploria strigosa* in 5 m of water at North Rock, Bermuda. The infected area, with black disease line and exposed white corallum, is at the lower left.

The disease seems to initiate at the margins of living colonies, or at irregularities such as areas of boring bivalves or barnacles, and to spread outwards from such points. We have seen no evidence for the initiation of the disease in the middle of healthy tissue. The disease does not always kill an entire colony, but rather dies out itself in time, leaving colonies with dead patches and living areas, the latter raised up by their continued growth.

Microscopic examination showed the disease to be a dense mat of bacterial filaments in which diatoms, ciliates and released zooxanthellae are embedded. The principal organism is the gliding bacterium *Beggiatoa*, a heterotroph requiring a source of sulphide such as H₂S to initiate its catabolic activities³.

By exposing healthy *Diploria* colonies to reducing conditions in aquaria, we have been able to foster *Beggiatoa*

infestations. In our experiments, reducing conditions over the coral surface were exploited by the sulphate-reducing anaerobic bacterium *Desulfovibrio*, which produced copious amounts of H_2S gas. Then *Beggiatoa* colonised the air- H_2S interface and attacked the coral tissue.

Fig. 2 Close-up view of the disease line on *D. strigosa*. Healthy tissue on right. The disease line is approximately 15 mm wide.

Such artificial infestation has not produced the localised dark line disease, but we find *Desulfovibrio* and *Beggiatoa* in the natural as well as in the artificial infections. The involvement of these microorganisms in both types of disease may be related only to decay (that is, the end stage of the disease). The close proximity of the *Beggiatoa* mat to healthy tissue in the natural disease, however, suggests its involvement at least in the spreading, and possibly in the initiation of the disease.

We have also occasionally observed the dark line disease on *Montastrea annularis*, and a disease net, similar to our artificially induced disease, on *Porites astreoides*. It seems likely that such diseases attack other corals in other reef areas, although because of the short life span of the disease (weeks to months) the numbers of diseased colonies will always be small. The large number of coral colonies on the reefs of Bermuda with dead patches, many of which could be disease-related, indicate that disease may be an important factor in coral ecology.

in association with callus cultures of non-legumes as well as with cultures of legume species which do not form nodules with the cowpea bacteria.

Three rhizobial strains were tested for contamination by non-symbiotic dinitrogen-fixing bacteria and maintained on a medium containing K_2HPO_4 0.5 g; $MgSO_4 \cdot 7H_2O$ 0.2 g; NaCl 0.1 g; yeast extract 0.5 g; $CaCO_3$ 0.5 g; mannitol 10 g l^{-1} water. Tissue cultures of brome grass (*Bromus inermis* Leyss.), wheat (*Triticum monococcum* L.), rapeseed (*Brassica napus* L.), sweet clover (*Melilotus alba* Desr.) and *Vicia hajastana* (Prairie Regional Laboratory⁵) were routinely examined by light microscopy, and subcultured on nutrient agar and in nitrogen-free media³. These tests confirmed the absence of microbial contaminants. Nitrogenase activity was established essentially as described for the soybean-*R. japonicum* combination⁶. Plant cells from suspension cultures were placed on a membrane lying on top of 50 ml low-nitrogen nutrient agar. After callus growth was established (7-20 d) the surface was infected with a small volume of *Rhizobium*. After a further 7-14 d, the vessel was sealed and endogenous ethylene production measured by gas chromatography after 1 h. Acetylene was injected, and after an hour another sample of the gas phase removed for analysis. The reduction of acetylene to ethylene is a positive indication of nitrogenase activity⁷. The plant cells were removed from the membrane for microscopic examination and dry weight determination.

Rhizobium sp. 'cowpea' 32H1 formed nitrogenase (C_2H_2) in association with plant cells of five field pea varieties, two soybean varieties, sweet clover and *Vicia hajastana*, as well as the non-legumes rapeseed, wheat and brome grass (Table 1). The possibility of infection by non-symbiotic dinitrogen fixing bacteria was excluded by subculturing positive callus-rhizobial associations on to yeast extract-mannitol agar, glucose-peptone agar and *Azotobacter* media³. There was no growth on glucose-peptone or nitrogen-free nutrient, and colonies observed on yeast extract-mannitol agar were microscopically indistinguishable from cowpea rhizobia. The dinitrogen fixing association described is aerobic^{6,8} and it is unlikely that it is due to contamination by *Klebsiella*, which usually only fixes anaerobically. The nutrient used⁶ has a low pH (5.5), and is unlikely to permit

Table 1 Acetylene reduction activity of associations of *Rhizobium* sp. 32H1 and various plant callus cultures

	Plant cells + <i>R. sp.</i> 32H1	Specific activity (nmol $C_2H_4\text{ h}^{-1}\text{ g}^{-1}$ dry weight) uninfected plant cells
Pea var. 'Century'	530	1.7
'Trapper'	1,250	8.8
MP766	109	2.5
MP7608	251	2.1
EMD	413	5.7
Soybean var. 'Acme'	353	—
'Mandarin'	7.3	—
<i>Vicia hajastana</i>	335	0.9
Sweet clover	108	3.6
Rapeseed	131	5.7
Wheat	83	0.6
Brome grass	323	0.2

Nitrogenase activity was determined by the reduction of C_2H_2 to C_2H_4 , followed by determination of the dry weight of callus. Each value is the mean of five samples. Rhizobial strains were obtained from Dr J. C. Burton, the Nitragin Company, 210 West Custer Ave, Milwaukee, Wisconsin 53209, USA. Strain 32H1 and 32Z3 were isolated from *Crotalaria* and strain 21A was isolated from *Chamaerista fasciculata*. Single colony isolates were prepared from dilution plates. All strains are motile Gram-negative rods, produced effective nodules on cowpea plant grew well on yeast extract-mannitol agar, and formed uniform pale colonies on yeast-mannitol-congo red agar. The three strains form a slight 'serum zone' in litmus milk after 10-14 d incubation². There was no growth on glucose-peptone agar, sporulation agar or severe standard nitrogen-free media³. Absence of *Klebsiella* was indicated by the lack of growth, acid or gas formation in anaerobic semi-solid peptone-carbohydrate media⁴.

Nitrogen fixation by a *Rhizobium* sp. in association with non-leguminous plant cell cultures

THE genus *Rhizobium* is characterised by its ability to elicit nodule formation and fix dinitrogen in roots of legumes and its species or groups are classified according to their legume host range. There is only one non-legume association reported, that of *Trema aspera* with a 'cowpea-type' strain of *Rhizobium*¹. Dinitrogen fixation by *Rhizobium* in the absence of a host plant has not yet been demonstrated. I report the production of nitrogenase (C_2H_2) activity in *Rhizobium* sp. 'cowpea strain' growing

dinitrogen fixation by *Azotobacter*, which usually prefer an almost neutral pH

Examination by light or electron microscopy showed that rhizobia grew on the surface of the callus and in cracks and intercellular spaces. Where bacteria were found in plant cells, destructive invasion had occurred. Moreover, the few such infected plant cells could not account for the observed acetylene reduction. In no case was a plant cell containing rhizobia observed which looked like a normal nodule cell. The bacteria always appear as rods rather than bacteroids, and no membrane surrounding the bacteria could be detected. The *Rhizobium*-plant callus association differs from the nodule system in its morphology and its reaction to plant growth regulators^{6,8}. A nodule-like infection process does not seem to be necessary to establish nitrogenase activity in the tissue culture system.

After the membranes were lifted to remove the callus for examination, a copious growth of rhizobia was often seen on the agar. The vessels were resealed, and acetylene again added. After an hour, ethylene production was measured, and it was found that 5–25% of the nitrogenase activity of the original systems could be accounted for by these bacterial cells not in direct contact with plant callus. The nitrogenase activity continues for 24 h, but does not persist when these rhizobia are transferred to nitrogen-free media.

Table 2 Acetylene reduction activity of associations of three strains of 'cowpea' *Rhizobium* and various callus cultures

Rhizobia sp Plant cell line	Specific activity (nmol C ₂ H ₄ per h per g dry weight)		
	32H1	32Z3	21A6
Soybean var 'Acme'	105	56	0
<i>Vicia hajastana</i>	178	26.5	23.9
Sweet clover	114	9.0	7.0
Rapeseed	205	19.0	20.6

Nitrogenase activity determined as in Table 1

The ability to form nitrogenase in the presence of non-host plant cells was also found in three cowpea strains (Table 2). Nitrogenase activity was, however, not obtained from *R. japonicum* or *R. leguminosarum* in the presence of non-legume tissue cultures.

Phillips⁹ has reported nitrogenase activity in an association of soybean cells and cowpea strain 32H1. This was not surprising, as *R. japonicum* and the cowpea groups are closely related, both belonging to the 'slow growing' rhizobia, and cross inoculation between soybean and cowpea has been found². Clover, pea and *Vicia* are nodulated by the 'fast growing' group of *Rhizobium* and nodulation of intact plants by cowpea *Rhizobium* is unknown².

The genes coding for nitrogenase are found in the bacteria^{10,11}. What elicits the expression of nitrogenase activity is unknown but the diffusible factor(s) involved are obviously not limited to legumes. The demonstration of nitrogenase in the presence of legume, rapeseed, wheat and brome grass cells suggests that some common plant product may be involved. It is likely therefore that in symbiotic dinitrogen fixation the species barriers are at the stages of infection and nodule formation, and not in the expression of nitrogenase.

I thank Mrs C Knapp for technical assistance, Dr W G W Kurz for his help in confirming the axenic nature of microbial and plant cultures, Dr T LaRue for his help in preparing the manuscript, Dr J C Burton for recommending medium and Dr R H Haskins for electron microscopy.

Nitrogen fixation by *Rhizobium* associated with tobacco and cowpea cell cultures

THE maxim that nitrogen fixation by the root nodule bacteria, *Rhizobium*, is restricted to a formal symbiotic association with specific legumes has recently been challenged. Trinick¹ showed that nodules formed on the non-legume *Trema canabina* (previously identified as *T. aspera*, M. J. Trinick, personal communication) by a strain of *Rhizobium* which nodulated *Vigna unguiculata* (cowpea), possess nitrogenase activity and fix atmospheric nitrogen. Soybean tissue cultures inoculated with *R. japonicum*^{2–4}, or with cowpea strains of rhizobia³, also possess apparently functional nitrogenase as determined by the acetylene reduction assay⁵. Several attempts have failed to demonstrate nitrogenase activity in cultured rhizobia⁶, including cowpea strains⁷.

We report nitrogenase-mediated acetylene (C₂H₂) reduction, and ¹⁵N incorporation, in associations of a strain of cowpea rhizobia (32H1) with cell cultures of a natural host, *V. unguiculata*, but more notably with a non-legume, *Nicotiana tabacum*. Furthermore, this strain of rhizobia reduced C₂H₂ when cultured adjacent to, but not in contact with, tobacco callus.

Cell cultures, derived from stem explants of *N. tabacum* cv Wisconsin 38 and *V. unguiculata* cv Poona, were maintained as 30-ml suspensions in Schenk and Hildebrandt⁸ (SH) medium with 2,4-dichlorophenoxyacetic acid (9 μM) and kinetin (0.2 μM) in 250 ml flasks on a gyratory shaker (100 r.p.m.) at 29°C in the dark. A culture of strain 32H1 (J. C. Burton, Nitragin Co., Milwaukee, Wisconsin⁹) was checked for purity by two successive isolations of single colonies on yeast-mannitol agar. Actively growing plant cell suspensions were inoculated with 2 × 10⁸ bacteria (1 ml), shaken for 48 h, centrifuged, and washed in cell culture medium. Aliquots (0.8 g fresh weight) of the pellet were spread on filter paper, drained of excess liquid and the cells and filter paper incubated on the surface

Table 1 Acetylene-dependent ethylene production* by 32H1-plant cell associations

	<i>N. tabacum</i> (nmol C ₂ H ₄ per g dry weight per hour)	<i>V. unguiculata</i> (nmol C ₂ H ₄ per g dry weight per hour)
GLN medium†	106 ± 21	7 ± 2
RN medium	118 ± 8	6 ± 2

*Cultures were sealed with serum stoppers and assayed after 2 h for endogenous ethylene (C₂H₄) which was found only in uninoculated tobacco cells (<7 nmol g dry weight⁻¹ h⁻¹). The gas phase was replaced with a mixture of 20% O₂, 20% C₂H₂, 60% argon and after 2 h, the reduction of C₂H₂ to C₂H₄ was measured by gas chromatography. Acetylene reducing activity (nmol C₂H₄ per g dry weight per hour) was corrected for endogenous C₂H₄ production where applicable. The limit of resolution was 0.5 nmol per g dry weight per hour in 2 h assays.

†SH medium⁸ without phytohormones and with major salts replaced by (in mM) KH₂PO₄ (2.2), CaCl₂ · 2H₂O (0.7), KCl (0.9) and MgSO₄ · 7H₂O (0.3) and with decreased inositol (0.6) and added glutamine (10) and glycine (0.03), 10 ml media in 18 ml bottles.

‡SH medium without phytohormones and with KNO₃ and NH₄H₂PO₄ replaced by (in mM) NH₄NO₃ (1.5) and K₂HPO₄ (2.9) plus added glucose (50), 12 ml media in 28 ml bottles.

of plant culture media slants at 29°C in the dark. These and control cell cultures were assayed for acetylene-dependent ethylene production (Table 1) after 10 d.

Nitrogenase activity, indicated by C_2H_2 reduction, was appreciable in the 32H1-tobacco cell associations, and low but positive in the 32H1-cowpea cultures (Table 1). There was no C_2H_2 reduction by control plant cells or by 32H1 cultured alone on RN or GLN media, or by 32H1 on yeast-mannitol agar. The mean activity of all inoculated tobacco cultures was comparable to the activity reported for *Rhizobium*-soybean associations²⁻⁴, but there was less variability under our conditions. The rate of C_2H_2 reduction by six inoculated tobacco cultures on RN medium was linear for 6 h but declined by 40% after 20 h, activity in the two other replicates declined after 2 h.

There was copious growth of rhizobia in inoculated tobacco cultures and on the exposed and underlying surface of the agar slants. When the filter paper with inoculated cells was removed and discarded, the residual rhizobia on the slant maintained nitrogenase activity for 8 h at 2.2 nmol ethylene per culture per hour. This was 16% of the average value for undisturbed cultures.

The indication that the rhizobia possessed nitrogenase activity, and that activity depended on the presence of plant cells, was confirmed by growing a lawn of 32H1 on a GLN agar plate to within 5 mm of uninoculated tobacco callus. Bacterial growth was enhanced close to the tobacco callus, and after 7 d, agar segments (2.3 cm²) containing only bacteria, only callus, or neither, were excised and assayed. The segments with rhizobia reduced C_2H_2 at 0.8 nmol per segment per hour and activity was linear for 8 h, declining to 60% after 60 h. No activity was found in the other segments or in 32H1 cultured in the absence of plant cells.

Fourteen day old 32H1-tobacco cell associations on GLN agar slants were exposed to an atmosphere of 20% O₂ and 80% N₂, containing 80 atoms per cent ¹⁵N, for 28 or 42 h. The inoculated cells on filter paper and the underlying bacteria from the agar were removed separately, and ¹⁵N enrichment of the samples determined by mass spectrometry. The values for the cells were 0.034 and 0.039 (28 h) and 0.048 (42 h), while the corresponding values for the bacteria were 0.461, 0.612 and 0.483 atoms per cent excess compared with values of zero for identical material incubated in air. These highly significant ¹⁵N enrichments conclusively verify that the C_2H_2 -reducing activity observed in these experiments was due to nitrogenase.

The interest of these results depends on the evidence that our 32H1 culture was an uncontaminated strain of *Rhizobium* and that the plant cell suspensions were uncontaminated. Our culture of 32H1, initially purified by two successive single colony isolations, was slow-growing on yeast-mannitol agar and was both culturally and microscopically (Gram negative, motile rods) uniform. There was no growth, aerobically or anaerobically under N₂, on N-free or on yeast-peptone media, whereas *Klebsiella pneumoniae*, M5a1, grew rapidly under these conditions. Cowpeas growing in sterilised vermiculite-perlite were inoculated with a suspension of 10⁸ bacteria ml⁻¹, or a 10⁷ dilution of this, and produced nodules within 7 and 14 days, respectively, mature nodules reduced C_2H_2 . Bacteria reisolated from nodules were uniform, culturally identical to the parental 32H1, and formed C_2H_2 -reducing associations with tobacco cells. We verified the homogeneity of our 32H1 culture by producing both C_2H_2 -reducing associations with tobacco cells and nodules on cowpea with each of 15 single colonies isolated from the original culture, these isolates, cultured alone on GLN medium, did not reduce C_2H_2 . Only slow-growing bacteria similar to our parental 32H1 were recovered from each of the 15 inoculated tobacco cell suspensions. Uninoculated tobacco cell suspensions, cultured on yeast-mannitol, yeast-peptone, or under N₂ on N-free media, showed no evidence of bacterial contamination. We are confident that our 32H1 culture was a pure strain of

Rhizobium and that the tobacco suspensions were uncontaminated.

Our results indicate that the genetic information for nitrogenase is encoded in *Rhizobium*, as suggested by other evidence^{7,10,11}. Expression of the nitrogenase gene appears to depend on a diffusible factor secreted by plant cells.

We acknowledge the help of Dr J. J. Child in the experiments with separately cultured bacteria and callus, and thank Drs F. J. Bergersen and J. D. Pagan for discussion during the final preparation of the manuscript, Mr G. L. Turner for mass spectrometry and Ms J. Adamson and Ms M. Ashby for technical assistance.

An attempt to separate fractions rich in human Y sperm

THE desire to predetermine sex before conception and thus alter the natural sex ratio has led many investigators to seek methods of separating the populations of X- and Y-bearing sperm and over the past 50 years, a number of claims of success have been made. Ericsson *et al.*¹ described a technique for the isolation of fractions rich in human Y sperm. On repeating the methods outlined in their paper, we were unable to find any evidence of enrichment of human Y sperm.

Initially, human semen was obtained from a hospital clinic, but there were two disadvantages, first, many of the samples showed poor sperm density and motility, and second, the time between ejaculation and reception of the semen at the laboratory was very variable. Later, an arrangement was made for seven anonymous volunteers to provide normal semen which could be used within 3-4 h of ejaculation. On arrival, all semen samples were examined on a warmed stage under a light microscope and assessed for percentage motility and degree of progressive motility. With a reasonable sample, 70-75% sperm showed progressive motility initially.

The separation technique was essentially that described previously¹ except that the fractions were obtained from the

bottom of the column. The semen was prepared by diluting 1:1 (v/v) with Tyrode's solution, centrifuging at 2,500g for 15 min and then resuspending the sperm in Tyrode's solution to give a final sperm density of approximately $100 \times 10^6 \text{ ml}^{-1}$. The semen was kept at room temperature throughout.

Columns of bovine serum albumin (in Tyrode's solution) were prepared in Pasteur pipettes (internal diameter 5.7 mm), closed by a clip on soft polythene tubing at the point of tapering. By controlling the clip, the flow of liquid from the column was easily regulated. Three separation procedures were used.

(1) One-layer technique. Each column contained 0.9 ml bovine serum albumin (BSA) in Tyrode's solution, of set concentration—a 6% solution was used in this series of experiments. The resuspended sperm (0.5 ml) (approximately 50×10^6 sperm) in Tyrode's solution were layered carefully on top of the albumin solution and left for 1 h. The top sperm layer was then removed with a pipette and the lower albumin fraction (isolation fraction) was removed from the base of the column. The sperm were recovered from the albumin by centrifugation at 2,500g and washed once in Tyrode's solution. The sperm were then resuspended in a little Tyrode's solution and smears made for staining.

(2) Two-layer technique. This was the modification described by Ericsson whereby discontinuous gradients of albumin solutions were prepared within the same Pasteur pipette column. Fifteen per cent BSA solution (0.4 ml) was overlaid with 0.8 ml 6% BSA solution. Sperm, prepared and resuspended in Tyrode's as before, was applied carefully to the top of the column. The column was left for 1 h, then the top sperm layer was pipetted off and the column was left for a further 30 min before the separate albumin layers were drawn off slowly from the base of the column. The separate BSA fractions were centrifuged at 2,500g and the sperm washed in Tyrode's solution (usually only one washing) before smears were made for staining.

All smears were air-dried and fixed in methanol for 30 min. The smears were stained with 0.5% aqueous solution of quinacrine dihydrochloride (Atebrin, Gurr) for 8 min followed by a brief tapwater rinse and a brief deionised water rinse, before mounting in water with a sealed coverslip. The smears were examined under oil with a dark field condenser at $\times 1,000$ magnification, using a Leitz microscope with a mercury vapour lamp and BG12 and 38 exciter filters. The total number of sperm counted was around 200 per sample which is the number used in our routine procedure for assessment of sperm quality and morphology. The proportion of these with a fluorescent spot or F body within the sperm head was noted. In a study of this nature, the staining procedure is of paramount importance. We investigated the effect of the length of time on staining and found that 8 min gave us the most consistent results. The assessment of the Y sperm was done very critically in that, if there was any doubt at all as to the presence of an F body, it was assumed to be absent. Such rigorous assessment of the Y sperm would undoubtedly lower the apparent percentage present.

As an experimental control, smears were made of untreated semen before preparing the sample for column separation. These smears were fixed, stained and examined at the same time as the experimental smears. We also investigated the effect of BSA on the staining process and in our hands we found that the presence of BSA did not affect the staining and difficulty was only encountered when we attempted to use 20% BSA.

Tables 1–3 show the results of 19 experiments in which a total of 14,374 sperm were counted. The presence of a fluorescent spot within the sperm head was taken to denote a Y-bearing sperm.

As can be seen from the tables of results, no positive increase in the proportion of Y sperm was achieved by passing the sperm through columns of BSA solutions. It might seem from the results that there is an increase in the number of X sperm. This is most likely because of the rigorous criteria which we applied to

Table 3 Three-layer technique

(3) Three-layer technique. The column was prepared by layering decreasing gradients of 20%, 15% and 10% or 6% BSA solutions over one another in 0.3 ml volumes. The top layer was 0.5 ml resuspended sperm in Tyrode's solution. The column was left for 1 h before the top layer was pipetted off and then for a further 60 min before the albumin fractions were drawn off. The sperm were removed from the separate BSA fractions by centrifugation at 2,500g and usually washed once in Tyrode's solution before smears were made for staining.

the identification of the Y sperm and does not indicate an actual increase in the number of X sperm.

Separation is dependent on the progressive motility of the sperm. We encountered difficulty in resuspending the sperm evenly after centrifugation. The process of washing the sperm and removing the seminal plasma resulted in a reduction in the percentage of progressively motile sperm in the first layer of the column. Clumps of sperm were formed which were so large that they could be seen to fall through the albumin layers under

gravity. The multiple layer techniques seemed to be preferable to the one-layer procedure because sperm were not subjected to centrifugation and resuspension before being placed on further albumin columns to complete the separation.

We have been unable to confirm the results obtained by Ericsson *et al*¹. The crucial parts of the procedure are the staining process and the subsequent identification of Y sperm. The standardisation of our staining technique and the criteria which we applied to the identification of the Y sperm are not responsible in our opinion for the negative results which we have obtained.

Failure to confirm separation of X- and Y-bearing human sperm using BSA gradients

THE ability to predetermine the sex of offspring before conception would have significant clinical and sociological implications in man¹ and would have great economic benefit if applied to the breeding of livestock. The claim of Ericsson *et al*² that human spermatozoa bearing Y chromosomes can be separated from sperm containing X chromosomes by passage through a medium containing bovine serum albumin (BSA) or ovalbumin, is therefore of some importance. We have attempted to repeat the experiments to confirm these findings and report here our failure to do so.

The experiments of Ericsson *et al*² yield two important conclusions. First that it is possible to separate the more motile fraction of human spermatozoa by layering a suspension of sperm in Tyrode's solution over various concentrations of BSA in single or multiple steps, when the more motile sperm enter the layers of higher concentration while the less motile sperm are retained within the Tyrode's solution or the less dense layers. Second, that sperm selected for increased motility in this way turn out to be predominantly Y-bearing sperm for example in two experiments where sperm motility was

Fig 1 *a*, Quinacrine stained spermatozoa showing the presence (arrowed) or absence of the fluorescent Y body. *b*, Spermatozoa from sample 5 before layering over BSA, showing the heterogeneous morphology of the sperm heads. *c*, Spermatozoa from sample 5 after layering over BSA (final isolate) showing a homogeneous morphology of sperm heads.

increased from around 65% to 98%, the percentage of Y-bearing sperm was reported to have increased from around 50% to 80%. In these experiments, the sex chromosome status of spermatozoa was ascertained by scoring for the presence or absence of a brightly fluorescing Y body (equated with the Y chromosome, see Fig 1*a*) in samples stained with quinacrine dihydrochloride³⁻⁵. Our work confirms the first conclusion but not the second.

A series of initial experiments was performed to test the effects of various concentrations of BSA and of different fixation procedures which might influence the fluorescent staining and Y-body detection in spermatozoa. It was found

Table 1 Sperm motility (%) and morphology*

Individual (Sample no.)	Control untreated (a)	Washed in Tyrode's and centrifuged (b)	Top layer	10% BSA	15% BSA	25% BSA
1	50 (25)	30	1			80 (50)
2	40 (—)	20	10			70 (—)
3	70 (67)	40	40	1	10	50 (77)
4	80 (51)	20	2	5	12	80 (78)
5	60 (51)	60	2	7	70	90 (68)
6	80 (64)	80	2	30	80	100 (84)
7	30 (22)	30	1	2	25	75 (88)
8	55 (20)	50	4	7	20	89 (94)

* Figures in parentheses are estimates (%) of sperm with normal morphology based on 100 spermatozoa per sample. The remaining entries are data on sperm motility based on a minimum of 100 sperm per sample.

The difference in motility (%) between (a) and (b) in samples 1-4 is the result of centrifugation in Tyrode's at 1,750g. There is no difference in motility (%) between sperm in untreated semen and samples washed and centrifuged at 800g, compare (a) and (b) for samples 5-8.

* The samples from subjects 1 and 2 were subjected to a single-step and the remainder to a three-step isolation procedure

that the efficiency of detecting a Y body was not influenced by BSA concentrations over a range of 6–25%, although higher background fluorescent levels were observed at the higher concentrations even though the samples had been washed four times in Tyrode's solution. Better fixation and staining was obtained from suspensions of sperm fixed in methanol acetic acid (3:1) than in methanol alone.

In the experiments reported here, semen samples were obtained from each of five healthy volunteers and three males attending a subfertility clinic. Each sample was subjected to either the simplest single-step, or the most efficient three-step continuous gradient, described by Ericsson *et al.*² In all cases the sperm count, volume and motility were estimated on the fresh specimen and a smear was prepared for morphological studies. The remainder of the sample was washed in Tyrode's solution (1:1) and centrifuged at 4,000 r.p.m. (1,750g) for 15 min and resuspended in Tyrode's solution at a concentration of 1×10^8 sperm ml⁻¹.

In the first four specimens studied it was noted that sperm motility was reduced after washing and centrifugation at 1,750g (see Table 1) and further experiments were carried out to examine possible effects of centrifugation on sperm motility in Tyrode's solution. It was found that 800g (2,000 r.p.m.) was the maximum centrifugal force with no adverse effect on sperm motility in Tyrode's solution and this was used in the later experiments. This effect on motility was only observed after centrifugation of sperm in Tyrode's solution and was not apparent when sperm were centrifuged in BSA/Tyrode's solutions.

Single-step gradients were set up in Pasteur pipettes by layering 0.5 ml of a suspension containing 1×10^8 sperm ml⁻¹ on to the top of 0.9 ml of 25% BSA (ref. 2). Continuous gradients consisting of 0.3 ml of 10%, 15% and 25% BSA as described by Ericsson *et al.*² were layered on top of each other in Pasteur pipettes and then 0.5 ml of the sperm suspension was carefully layered on top. The columns were left at room temperature for 1 h when the top layer (Tyrode's plus sperm) was removed by pipette. In the continuous gradients the 10% BSA layer was pipetted off after a further 30 min and the final layers after another 30 min. In the single gradients the top layer and the final layer were removed after 1 h. After removal, each layer was washed four times in Tyrode's solution and fixed in methanol acetic acid (3:1). The fixed suspensions were dropped on to slides and air dried before staining in an aqueous solution of quinacrine dihydrochloride for three minutes. All slides were coded, randomised and scored blind for the presence of a Y body in 100 or 200 sperm from each of two slides made from each layer of each gradient. The observations were made using a Leitz Ortholux microscope fitted with the appropriate fluorescence attachments⁶.

Our results show that the percentage of Y-bearing sperm in the final isolates does not deviate significantly from that of the controls (Table 2) and thus contradict those of Ericsson *et al.*² They do, however, demonstrate that isolation seems to be dependent on sperm motility and that as Ericsson *et al.*²

describe, the non-motile sperm are initially retained in the upper less dense layers (Table 1).

It is well known that spermatozoa in a semen sample from normal fertile human males, in contrast to most other mammals, show considerable morphological heterogeneity⁷ and include a significant proportion of immature cells. The percentage of so-called 'normal' forms (defined largely on shape and structure of head and tail) is, in our laboratory, very often below 50% and rarely above 70%. As Ericsson *et al.*² have noted, selection for motility also results in increasing the proportion of morphologically normal sperm. Our own data (Table 1) clearly support and confirm this conclusion (compare with Fig. 1b and c). With this technique, however, the yield of normal motile sperm is low (between 1% and 5% of the original sperm input) and, although dependent on the quality of the initial sample, could doubtless be increased with improved methods.

There is no doubt, therefore, that fractionation of sperm samples using BSA gradients provides a method for selecting morphologically normal sperm of high motility so the technique might prove useful in the treatment of male subfertility. A series of ejaculates could be treated by the BSA method and the isolates stored in liquid nitrogen until a sufficient sperm concentration is achieved.

Finally we emphasise that our results do not support the contention that there is a differential motility between X- and Y-bearing spermatozoa that can be exploited to separate these cell types using the methods described by Ericsson *et al.*²

We thank Dr D. Richardson for allowing us access to his panel of sperm donors, and Mrs J. Fletcher, Messrs N. Davidson and G. Martin for technical assistance.

Sex and age differences in human platelet aggregation

MALES stand at risk in many pathological states¹, especially cardiovascular disease, in which there is a statistically significant higher mortality in men than women². We have described³ a sex difference in platelet responsiveness in rats and guinea pigs where platelets from males were significantly more sensitive to aggregating stimuli than those from females. Increased platelet responsiveness has been detected in humans,

in thromboembolic disease⁴ and after acute myocardial infarction⁵. Indeed, the principal *post mortem* finding in subjects who died suddenly is occlusion in the pulmonary circulation due to platelet aggregation⁶. We have suggested³ that platelet sensitivity is mediated by the androgenic steroids and that androgens contribute to the incidence of thrombotic disease.

In contrast to the situation with synthetic contraceptive steroids⁷, few variations have been observed in the response of human platelets to endogenous sex hormones, although adenosine diphosphate (ADP)-induced aggregation in women was increased during ovulation and in pregnancy⁹. Zahavi *et al.*⁸ reported that platelets from normal women on the second day of menstruation were more responsive to aggregation than those from normal men. Platelet adhesiveness in the presence of an encephalitogenic factor was also greater in women than men¹⁰, although this was not observed in another study where platelet adhesiveness was estimated directly¹¹.

Fig. 1 Effect of sex and age on human platelet aggregation. PRP was prepared from the blood of human male, mean age 23.2 (hatched symbol), mean age 42.4 (hatched/dotted symbol) and female donors, mean age 25.2 (open symbol), mean age 45.9 (dotted symbol), at the same time of day²¹. The platelet count was adjusted to $\sim 200,000 \text{ mm}^{-3}$ with autologous platelet-poor plasma (PPP). The light transmission through PRP and PPP was taken as 0% and 100% aggregation respectively. The extent of maximum aggregation (T_{max} ¹⁷, in light transmission units) was recorded following addition of an aggregating agent to 1 ml of PRP (37°C , 900 R.P.M.) in a siliconised tube. The response to ADP (Equine muscle, Sigma, $1 \mu\text{g ml}^{-1}$), adrenaline (Parke Davis, $10 \mu\text{M}$), collagen ($50 \mu\text{l}$ of suspension)²² and arachidonic acid²³ (1 mM) in 35 estimations ($\pm \text{s.e.m.}$) is indicated.

The mortality rate from cardiovascular disease increases exponentially with age in both men and women, although it is always higher in men and reaches a maximum in the fifth decade of life¹². We have now found that platelet sensitivity to aggregant stimuli similarly increases with age, especially in men, and that donors classified as high mortality risk (on an age basis) have enhanced platelet responsiveness when compared with younger donors of lower risk.

Blood samples were drawn from the cubital vein of resting human volunteers into 3.8% (w/v) trisodium citrate (1 part anticoagulant to 9 parts blood). Donors were screened for recent history of medication¹³, cigarette smoking¹⁴ and no samples were taken within 3 h of a meal¹⁵. Platelet-rich plasma (PRP) was prepared as described previously¹⁶ and maximum aggregation (Fig. 1) was assessed routinely 1 h after sampling, in an aggregometer (Payton Associates, New York). This

parameter is linearly proportional to platelet count and aggregating agent concentration¹⁷ and was observed here to give good reproducibility between repeated tests on the same donor. Primary aggregation, monophasic with pronounced disaggregation in response to ADP ($0.5 \mu\text{g ml}^{-1}$) and secondary aggregation, monophasic exponential or biphasic with minimal disaggregation in response to ADP ($5 \mu\text{g ml}^{-1}$), was demonstrated in each sample before use.

In one study, 19 healthy men, 21–25 yr old (mean 23.2) were compared with 19 healthy women, 21–26 yr old (mean 25.2). In a second study, 17 normal men, 38–47 yr old (mean 42.4) were compared with 16 premenopausal women, 36–50 yr old (mean 45.9). Samples from women were taken at random with respect to the menstrual cycle⁸, but not during menstruation. In a third study, postmenopausal women, 56–58 yr old (mean 57.0) were compared with normal men, 55–62 yr old (mean 58.5). These postmenopausal women were not on oestrogen supportive therapy. Mean values for the platelet response to various aggregating agents in these groups were compared, and the appropriate Student's *t* statistics calculated.

The primary aggregation (reversible) induced by ADP in platelets of young healthy women (mean age 25.2) was significantly ($P < 0.001$) increased over the values obtained in males (mean age 23.2) (Fig. 1). This female platelet sensitivity apparently depended on the degree of aggregating stimulus, and was 3.7 times greater than male sensitivity in response to ADP ($1 \mu\text{g ml}^{-1}$) and 2.0 times greater in response to ADP ($2 \mu\text{g ml}^{-1}$). These data are in accord with the report⁸ that female platelets were more responsive than male platelets to ADP ($0.6 \mu\text{g ml}^{-1}$ and $6.0 \mu\text{g ml}^{-1}$). They are, however, in contrast to our observations in the rat and guinea pig, where male platelet sensitivity was significantly greater than female sensitivity at concentrations of ADP from 0.1 to $10 \mu\text{g ml}^{-1}$. Primary and secondary (irreversible) aggregation induced by adrenaline was also significantly greater (1.8 times, $P < 0.01$) in human females than in males (Fig. 1). No significant difference was observed in secondary aggregation of these platelets induced by either collagen or arachidonic acid.

In the high risk age group (mean 45.7), platelet aggregation in response to primary and secondary aggregating stimuli was significantly ($P < 0.005$) enhanced in both males and females, when compared with the low risk group (mean 24.2). Female platelets were again more responsive (1.25 times) to ADP ($1 \mu\text{g ml}^{-1}$) than male platelets ($P < 0.05$) (Fig. 1). This female/male ratio of sensitivity was, however, significantly less than that in the low risk age group. Indeed, there was no significant sex difference in response to ADP ($2 \mu\text{g ml}^{-1}$) in the older group.

The change in sensitivity ratio was reflective of a significantly ($P < 0.01$) greater increase in male platelet responsiveness in the high risk group. For example, platelet aggregability increased 4.8 times in response to ADP ($1 \mu\text{g ml}^{-1}$) in males and only 2.0 times in females. Results were similar with adrenaline-induced aggregation. In the high risk group there was no significant difference ($P > 0.05$) between males and females in their response to adrenaline (Fig. 1). This is in contrast to the female/male ratio of 1.8 determined in the low risk group and represents a twofold increase in male platelet sensitivity.

The marked sex difference in platelet sensitivity observed in both high and low risk groups could be the consequence of an interaction of platelets with sex hormones. We have demonstrated that natural sex hormones may attenuate platelet behaviour *in vitro* and *in vivo*³. To determine the effects of oestrogen withdrawal¹⁸, platelets from premenopausal women (mean age 45.9) were compared with those from postmenopausal women (mean age 57.0). There was no significant difference in platelet responsiveness to either ADP or adrenaline between these groups, suggesting that oestrogens are not responsible for the enhanced platelet sensitivity in females.

In addition, incubation of male or female human PRP with oestradiol ($1 \mu\text{g ml}^{-1}$) or with progesterone ($1 \mu\text{g ml}^{-1}$), under conditions which detect possible platelet-sensitising effects of

Fig 2 Effect of testosterone *in vitro* on human platelet aggregation. Human male (open symbol) and female (hatched symbol) PRP (platelet count $\sim 200,000 \text{ mm}^{-3}$) was incubated in the presence or absence of testosterone ($1 \mu\text{g ml}^{-1}$) for 30 min at 22°C . Potentiation (%) of aggregation to ADP ($1 \mu\text{g ml}^{-1}$), adrenaline ($10 \mu\text{M}$), collagen ($30 \mu\text{l}$ of suspension) or arachidonic acid (1 mM) over that in the control (vehicle-treated) plasma is illustrated. The mean of 25 estimations ($\pm \text{s.e.m.}$) is indicated.

the sex hormones (M J, E R, and P W R unpublished) resulted in only 10.4 ± 2.4 and $10.9 \pm 0.3\%$ increases in responsiveness to ADP. This was significantly ($P < 0.01$) less than after incubation with androgenic steroids. Testosterone ($1 \mu\text{g ml}^{-1}$) enhanced the aggregating capability in response to ADP by 33.6 ± 3.9 and $24.9 \pm 2.1\%$ in male and female platelets respectively (Fig 2). It is interesting that testosterone was also more effective than either oestradiol or progesterone in inducing sensitivity to secondary (irreversible) aggregating agents such as adrenaline, collagen and arachidonic acid. Aggregation of both male and female platelets induced by arachidonic acid was very responsive to androgen *in vitro*, exhibiting 75.0 ± 1.9 and $97.0 \pm 4.5\%$ increases in sensitivity respectively (Fig 2).

Thus we have demonstrated that (a) there is a significant sex and age difference in human platelet sensitivity to aggregating stimuli, (b) female platelets are more responsive than the corresponding male platelets, (c) platelet responsiveness in both sexes increases with age, male sensitivity increasing at a greater rate than female sensitivity, and (d) cardiovascular disease high risk age groups exhibit enhanced platelet responsiveness when compared with low risk groups.

The sex difference in platelet sensitivity may be intrinsic to the platelet. Our evidence indicates, however, that natural oestrogenic and progestogenic steroids have minimal effects on platelets both *in vivo* and *in vitro*, although androgenic steroids were significantly active *in vitro*. Platelet sensitivity may equally be determined by interaction with various clotting factors, fibrinogen, plasminogen and fibrinolytic inhibitors, the levels of which are sex hormone-dependent¹⁹.

Disaggregation⁵ and adhesiveness¹¹ of platelets is apparently not related to the age of the donor. Male platelet responsiveness, however, increased significantly with age and concurrent with other androgen-related risk factors such as pressor sensitivity²⁰, blood viscosity¹ and serum cholesterol, phospholipid and tri-

glyceride levels¹² may contribute significantly to the incidence of arterial disease.

Endometrial cell calcium and oestrogen action

ADMINISTRATION of oestrogen to an ovariectomised or immature rat promotes a rapid increase in the content of water and univalent electrolytes in uterus and vagina^{1,2}. Although alterations in the uptake and retention of calcium and other divalent cations by several hormone-responsive tissues have been reported following long term administration of oestrogen *in vivo*³⁻⁵ and during the oestrous cycle⁶, no information is available on the cellular exchange, if any, of calcium shortly after administration of oestrogen in sensitive targets. In view of evidence suggesting a critical role for calcium in the initiation and/or regulation of cell growth and metabolism⁷, consideration of the potential involvement of this cation in the uterine response to oestrogen is important to analysis of steroid hormone action at the cellular level. Using endometrial cell suspensions isolated from the uteri of ovariectomised rats⁸, we have now shown that physiological levels of oestradiol-17 β influence rates of cellular calcium exchange as early as 2.5 min after *in vitro* addition of hormone.

Endometrial cells were isolated and maintained as before⁸ and suspended in Ringer solution composed of 136.9 mM NaCl, 2.7 mM KCl, 0.7 mM CaCl₂, 0.6 mM MgCl₂, and buffered at pH 7.4 with 8.1 mM Na₂HPO₄/1.5 mM KH₂PO₄, in the presence of 1 mM Na pyruvate. Calcium uptake by the isolated endometrial cells was determined from accumulation of ⁴⁵Ca²⁺ (New England Nuclear Corp.) A 40-ml cell suspension ($\sim 10^6$ cells per ml) in a 50-ml plastic Erlenmeyer flask was placed over a submersible magnetic stirrer in a water bath at 37°C and gassed with O₂. After a brief equilibration period, 50 μCi of ⁴⁵CaCl₂ was added (zero time) and incubation continued. Samples of medium were taken at selected intervals after addition of the isotope. For each time interval, two samples (1.5 ml each)

Fig 1 Calcium uptake of isolated endometrial cells is expressed as (d.p.m. per mg cell protein)/(d.p.m. per nmol medium calcium). After a 60 min basal period, oestradiol-17 β (○), to a final concentration of 1×10^{-8} M, or its vehicle, ethanol (●), to a final concentration of 0.02%, were added *in vitro* to experimental and control suspensions, respectively. The incubations were then continued for 90 min. Each point (mean \pm s.e.m.) represents data from three to six independent experiments.

were removed and transferred into two plastic centrifuge tubes containing 11 ml ice-cold, isotonic choline chloride, buffered at pH 7.4 with Tris. The tubes were immediately centrifuged (at 4°C in a Sorvall SC2B centrifuge) at 600g for 1 min. The supernatant was decanted, and the tubes were inverted to drain overnight. Double-distilled deionised water (4 ml) was added to the cell sediment which was homogenised with a high-intensity ultrasonic probe. Aliquots of sonicate were taken for determination of cell protein⁹ and ^{45}Ca by liquid scintillation counting. Oestradiol-17 β , where indicated, was added to the medium to a final concentration of 1×10^{-8} M. 60 min after zero time, the control flask received vehicle alone.

Efflux of ^{45}Ca was determined with cells preloaded with isotope by the addition of $^{45}\text{CaCl}_2$ (final concentration of $50 \mu\text{Ci ml}^{-1}$), followed by 60 min of incubation. The suspension was washed by centrifugation twice with buffer for 1-min periods at 600g. The final sediment was resuspended in 6 ml of ^{45}Ca -free Ringer solution and one-half distributed into each of two stop-flow chambers. The chambers, made from polycarbonate, were mounted on a filter funnel equipped with a stopcock which could be opened for rapid filtration of the suspension medium through a 0.45- μm Millipore filter. The top of the chamber was sealed with a rubber serum cap through which O_2 and wash solutions could be introduced by means of syringe needles. This assembly was immersed immediately above a submersible stirring magnet in a water bath at 37°C. A 1 mm bar magnet stirred the suspension continuously.

Isotope desaturation began with the addition of cell suspensions to the chambers. The medium was replaced at selected times, when cells were washed with 2×3 ml 'cold' Ringer solution with the stopcock open. The stopcock was then closed and 3 ml of fresh medium was delivered to resume the desaturation. Washing was completed within 30 s. Aliquots of the spent media were taken for liquid scintillation counting of ^{45}Ca . After desaturation, cells were collected and sonicated as above. Aliquots of sonicate were taken for determination of total cell ^{45}Ca and protein as above.

• Figure 1 shows that from zero time to 60 min, accumulation of calcium in the cells in the absence of test agents was exponential, similar to that described for other mammalian cells¹⁰. Addition of oestradiol increased Ca^{2+} uptake to 153% of control levels in 10 min ($P < 0.05$) with a peak

at 230% of controls ($P < 0.01$) within 30 min. Uptake declined to 50% of control values ($P < 0.01$) by 45 min and then gradually rose towards the baseline.

To test whether oestrogen increased net calcium accumulation in part by inhibiting efflux, we measured calcium efflux rate coefficients in the presence and absence of oestradiol-17 β , added *in vitro*. Cells were preloaded with isotope for 60 min and then distributed equally into an experimental and a control group. Figure 2 shows that during the first hour of desaturation, represented by the basal period, efflux occurred at essentially the same rate in both samples. After addition of oestradiol at 60 min, however, $^{45}\text{Ca}^{2+}$ efflux began to oscillate both above and below control levels. It declined to 87% of control after 2.5 min ($P < 0.05$), rose to 121% of control within 5 min ($P < 0.05$) and then declined to its lowest ebb, at 74% of control ($P < 0.001$), 40 min after addition of hormone. Thereafter, it remained depressed ($P < 0.05$) to the termination of desaturation measurements at 120 min.

The relationship of these early changes in calcium flux to later metabolic effects of oestradiol was considered in further experiments. We have shown previously that cortisol can block the stimulatory effect of oestradiol on glucose metabolism of isolated endometrial cells⁸. The action of 3×10^{-8} M cortisol hemisuccinate (Solu-Cortef, Upjohn) and its interaction with 1×10^{-8} M oestradiol in affecting $^{45}\text{Ca}^{2+}$ accumulation were evaluated from measurements of calcium uptake taken for 30 min after addition of steroids to isolated cells, ethanol to a final concentration of 0.02% was added to suspensions of control cells. Cortisol alone did not affect Ca^{2+} uptake, for in its presence uptake was 95% of controls. Addition of cortisol immediately before exposure to oestradiol, however, abolished the expected increase of calcium influx within 30 min (94% of control). These results parallel those obtained for intestinal calcium transport which indicate that glucocorticoids antagonise vitamin D-induced absorption of calcium¹¹.

Our experiments demonstrate that physiological concentrations of oestradiol-17 β act *in vitro* to produce oscillations

Fig 2 The calcium efflux rate coefficient of isolated endometrial cells was calculated according to Isaacson and Sandow¹⁵. With the rate coefficient of the control group being taken as 100%, the changes in the oestradiol-treated group at each point were expressed as percentage of control. Additives were introduced *in vitro* at the concentrations indicated in Fig 1 after a 60-min basal period. Each point (mean \pm s.e.m.) represents data from three to seven independent experiments, points without s.e.m., however, are taken from the results of two experiments.

in the net calcium content of isolated endometrial cells by influences on rates of influx and efflux. Similar variations in the cellular content of calcium have been considered important in the action of other hormones¹². Other evidence also indicates that increments in cellular calcium accumulation precede and/or trigger cell division and growth^{6,7}, which is the end-point of oestrogen action in endometrium. Strict control of intracellular calcium seems to be achieved by regulation of fluxes across the plasma membrane and between the cytoplasm and subcellular organelles, such as mitochondria¹¹. It has also been reported that diethylstilboestrol blocks energy-dependent Ca^{2+} uptake by mitochondria isolated from the myometrium¹³. Collectively, these oestrogenic effects on calcium exchange must lead to marked changes in cytoplasmic Ca^{2+} activity, binding and redistribution at intracellular sites. The characterisation of calcium exchange in resting and oestrogen-stimulated endometrial cells, therefore, has significant bearing on the processes involved in metabolic and mitogenic responses to the hormone¹⁴.

This investigation was aided by grants from the US Public Health Service and the US National Science Foundation, and by general research funds of the University of California. Two biological activities regulating cell proliferation found in cultures of peritoneal exudate cells

WE have found two distinct biological activities in cultures of peritoneal exudate cells rich in macrophages. One consists of an inhibitory effect on cell proliferation, described previously, caused by a low molecular weight product¹, the other is a stimulatory effect brought about by a non-dialysable material. Both activities were found in the same culture fluid, and different kinds of cells exhibited different sensitivities to them. Our results offer a possible explanation for the discrepancies in the literature concerning the different effects of macrophages or their products on cells¹⁻⁷.

We cultured the peritoneal exudate from A/St or C57BL/6 mice injected 3 d previously, intraperitoneally, with 1.5 ml of a 10% (v/v) solution of proteose peptone (Difco). The cells were plated at a density of 10^7 or 2×10^6 cells per ml on 35 mm plastic dishes (Falcon) in RPMI-1640 culture medium supplemented with 5% foetal calf serum. After 24 h, the medium was collected, the cell monolayer

was washed, fresh medium was added, and the culture continued for 48 h. The activities of the culture fluids obtained during the first 24 h or from the 24-72-h period were tested. Most cells forming the exudate were typical macrophages as judged morphologically, during the first 24 h, 5-10% lymphocytes were present with the macrophages, but most were eliminated by the washing at 24 h. We tested the incorporation of ^3H -thymidine by EL-4 leukaemia cells, P815 mastocytoma cells, thymocytes and spleen cells cultured in the presence of various amounts of fluids from macrophage cultures. Results have been consistent for more than twenty different experiments. The main results shown in Figs 1-3 were obtained with a fluid from a culture of 10^7 cells per ml.

Incorporation of ^3H -thymidine into EL-4 leukaemia cells cultured for 8 h in the peritoneal cell supernatant was inhibited markedly (Fig 1). This inhibition correlated with that of cell mitotic activity and with the increase of cell density with time of culture¹. The culture fluid, if dialysed extensively against normal culture medium, lost all inhibitory activity. EL-4 cells cultured in dialysed culture supernatants incorporated the same amount of thymidine as cells cultured in normal medium. Another cell line, the mouse mastocytoma P815 used extensively in current *in vitro* studies of cell-mediated immunity, behaved as the EL-4 line, and its incorporation was inhibited markedly by the supernatants (data not shown).

Fig 1 Incorporation of ^3H -thymidine by EL-4 leukaemia cells cultured in the presence of different amounts of culture fluids from peritoneal exudate cells. Cells were cultured at a density of 5×10^5 per ml in plastic tubes for 8 h, the last 4 h in the presence of ^3H -thymidine (New England Nuclear Corp., 2 Ci mmol⁻¹). Each result is the mean of three culture tubes. Brackets refer to standard error of the mean. In this experiment, the EL-4 cells (a tumour line from C57BL/6 mice) were cultured in the presence of fluids from A/St mice. Identical results have been obtained if the cells are cultured in fluids from C57BL/6 peritoneal cells.

We examined for the amounts of inhibitor extracted by freeze-thawing the peritoneal exudate cells or released into the medium after culture for 24 h. The amounts of material (v/v) required to reduce by 50% the incorporation of ^3H -thymidine by EL-4 cells were determined. The amounts were 63% from cells lysed immediately after plating, 83% from cells lysed 24 h after plating, and 22% from the fluids after culture for 24 h. Thus, the inhibitory activity found in culture fluids was generated during the culture and did not result from lysed or dead cells. The chemical nature of this material is not known. In our previous experiment, we indicated that the material was resistant to tryptic digestion, to phosphodiesterase treatment, and to boiling and freeze-thawing¹.

The spontaneous incorporation of ^3H -thymidine into spleen cells cultured with the untreated supernatant was inhibited slightly. When these cells were cultured with

dialysed supernatants, c p m were the same as controls in the range of doses used, 10–50% (v/v) (In other experiments, a 75% concentration of the dialysed peritoneal cell supernatant increased incorporation of ^3H -thymidine by about 90%) If spleen cells were cultured in the presence of phytohaemagglutinin (PHA) for 3 d, there was an expected marked increase in incorporation (^3H -thymidine was present during the last 12 h of culture) (Fig 2) The culture conditions used here—3-d culture, 1640 medium with 5% foetal calf serum, 10^6 lymphocytes in 12×75 -mm plastic tubes, 12-h pulse of ^3H -thymidine, and 100 μl of 1:100 dilution of Difco PHA-P—were selected to produce optimal response The response to PHA was reduced markedly in the presence of peritoneal cell culture supernatant in agreement with our findings¹ The dialysed culture supernatant, however, not only lost its inhibitory property but increased the response of the spleen cells to PHA This experiment, therefore, revealed two activities differentiated on the basis of size, influencing the multiplication of spleen lymphocytes

Of particular interest are the results with thymocytes The conditions for thymocyte culture were identical to those used for spleen cells, except for the cell density, which was 5×10^6 cells per ml First, the untreated supernatants increased slightly the spontaneous incorporation of thymidine into thymic cells, the dialysed fluid, however, had markedly more activity (Fig 3) Clearly, the fluids contained a principle that stimulated ^3H -thymidine incorporation and which was partially masked by a low molecular weight inhibitor Thymocytes responded poorly to PHA as expected For example, the spontaneous c p m of thymocytes after culture for 3 d was 678 (mean of triplicate culture, s e m ± 115), PHA for 3 d increased this only to 1,337

Fig. 2 Spleen cells from A/St mice were cultured in the presence of various amounts of the supernatants and PHA Time of culture was 72 h, the last 12 h in the presence of ^3H -thymidine Cultured fluids were dialysed against ten times the volume of normal medium for 72 h, changing the dialysate on four occasions ●, Dialysed supernatant, ○, untreated supernatant

Fig. 3 Response of thymocytes to supernatants of peritoneal exudate cells For explanation see text a, No PHA, b, with PHA Symbols are as in Fig 2

(± 109) In agreement with the data of Gery *et al.*⁴, the untreated culture supernatant increased the PHA response of thymocytes up to $18,253 \pm 1,962$, at 10% (v/v) concentration This culture supernatant inhibited at high concentrations (more than 10%) The dialysed supernatant, on the other hand, was much more potent and showed, at the most, a small decline at high concentrations

In other experiments we have dissociated the inhibitory and stimulatory activities by varying the density of the peritoneal exudate cells All results described before were obtained with culture fluids obtained from 10^7 cells per ml plated in 35-mm plastic dishes A cell density of 2×10^6 per ml produced supernatants in which inhibitory activity was decreased in proportion to the reduction in cell density but in which stimulatory activity was maintained at about the same intensity

An inhibitor or a stimulatory factor for cell proliferation released from peritoneal exudate cells explains some of the divergent results previously published, but raises important points concerning their chemical nature and biological significance All evidence points to the macrophage as the source of both materials since peritoneal exudate cells devoid of lymphocytes released the same amount of activity (ref 1 and unpublished observations) The relationship between the state of maturation and/or activation of the macrophages and the two factors, however, are not clear It is possible that in a given situation inhibition or stimulation could result from such conditions as number of macrophages, anatomical relationship between macrophages and the target cell, the state of the macrophage and the nature of the target cell in question The two factors must now be considered with regards to the well known role of macrophages in immune induction⁵ and in cellular type of immunities⁶

Chromosomal variation and the establishment of somatic cell lines *in vitro*

WHEN somatic cells from a number of species are explanted *in vitro*, they may either completely fail to grow, or they may continue to divide for a limited number of generations, at a progressively lower rate and with decreasing plating efficiency. They will eventually die unless, from this "crisis", a new population emerges with altered properties (see for example ref. 1). This new population, the established line, is usually capable of existing indefinitely and its growth rate and plating efficiency progressively increase until they stabilise at a level characteristic of each individual line.

The chromosomal constitution of these established lines is virtually always different from that of the parental primary cells and it is still a matter of debate whether these karyotype changes precede or follow establishment.

A parasexual cycle of polyploidisation-segregation has been found in human fibroblasts before crisis² and together with the fact that senescent human fibroblasts can be rescued by cell fusion³—which is normally followed by chromosome segregation⁴—suggests that polyploidisation may be important for establishment, perhaps as a source of variability. As the number of centromeres is subject to certain restrictions⁵ and multipolar mitoses are frequent⁶ the polyploid fraction would be unstable and would tend to generate a whole range of new types, often pseudo or quasi-diploid. Such variations in gene balance would give greater opportunities for generating types capable of existing indefinitely. Therefore polyploidisation, no matter how induced, could promote the growth of primary cells explanted *in vitro*. To test this hypothesis, we used various treatments which ultimately induce polyploidisation to determine whether the treated cell populations showed a better adaptation to *in vitro* conditions.

Whole mouse embryo cells, 4 d after explantation, were treated with β -propiolactone inactivated Sendai virus to promote cell fusion and then seeded in agar. Four colonies developed from a total of 5×10^6 Sendai-treated cells whereas no colonies developed from 5×10^7 untreated control cells. This growth could not be caused by growth-promoting factors present in the virus suspension since the virus had no effect on sparse cells in monolayers. Moreover, cell fusion rather than simple cell aggregation seems to be responsible because the colonies grown in agar, when isolated, propagated in monolayer and replated in agar, showed a plating efficiency of approximately 10^{-4} .

Chick and hamster cells were also treated with polyploidising agents such as griseofulvin, cytochalasin B or inactivated Sendai virus. Whole embryo primary cells, 4 d after explantation, were trypsinised and either treated with inactivated Sendai virus (200 haemagglutinating units per ml for 30 min) and then plated at 1.5×10^4 cells cm^{-2} , or plated

at the same concentration and treated the next day with griseofulvin ($50 \mu\text{g ml}^{-1}$) or cytochalasin B (1 and $5 \mu\text{g ml}^{-1}$). (In the case of chick cells, the plating concentration was 10^4 cm^{-2} .) Ten hours later the drug was removed. After 3 d all dishes were trypsinised and the cells plated at 500 cm^{-2} (1,000 in the case of chick cells).

At this cell density the control cells did not grow whereas colonies developed in the other dishes. Some of these colonies were isolated and propagated in monolayer. They gave rise to established lines with a success rate greater than 0.3 in the case of mouse and 0.12 in the case of hamster. With chick fibroblasts no permanent lines were obtained but the proliferation time was extended (85 d in griseofulvin-treated cells compared with 40 d for the control).

The growth-promoting effect can also be measured in terms of mitotic index (Table 1). A few days after treatment the mitotic index increased but there was a concurrent decrease in the polyploid fraction. This indicated that the proliferating fraction might not be represented by polyploid cells but by some of their segregation products.

Table 1 Mitotic index and frequency of polyploids

Time (d)	Control		Cytochalasin treated	
	Mitoses (%)	Polyploid (%)	Mitoses (%)	Polyploid (%)
1	8.3	2.3	4.0	25.0
2	4.7	8.1	3.2	23.2
4	1.8	6.2	1.8	23.2
5	1.9	7.3	4.6	14.7
6	1.6	5.9	5.2	13.0

Mitotic index and frequency of polyploids (cells with more than 60 chromosomes) in whole embryo mouse cells treated with cytochalasin B. Primary mouse cells were trypsinised 4 d after explantation and seeded at 1.5×10^4 cells cm^{-2} . Next day cytochalasin B was added at $1 \mu\text{g ml}^{-1}$ and removed 18 h later (time zero). Each subsequent day coverslips were set up with 2×10^4 cells cm^{-2} . Next day colchicine was added and 3 h later the coverslips were stained.

This possibility was examined with cells from *Mesocricetus auratus* which are generally difficult to establish and tend to be pseudo-diploid and whose chromosomes are easily identified⁹⁻¹¹. We observed a progressive loss of viability *in vitro* with these cells. In six generations the plating efficiency dropped from 0.52 to less than 0.001 and the growth rate, initially 1.5 d^{-1} fell to 0.4 d^{-1} . This only occurred however, if the cell density was kept above 5×10^3 cells cm^{-2} , at lower cell densities, untreated cells did not grow, whereas cells treated with any one of the polyploidising agents gave rise to colonies, 13 of which were isolated and developed into established lines. But when we seeded treated or untreated cells at densities ranging from 5×10^3 to 5×10^4 cells cm^{-2} and subsequently passaged the confluent dish that had the smallest inoculum, we succeeded in establishing lines from these mass cultures. The properties of these lines, 7 months after continuous cultivation, were indistinguishable from those of the 13 lines obtained after polyploidisation in respect of plating efficiency, which varied between 0.05 and 0.40, and growth rates, which were between 0.8 and 1.5 d^{-1} . When tested 5 months after explantation, two treated and one control line gave palpable tumours in less than 1 month when 3-month-old animals were injected subcutaneously with no fewer than 10^5 cells.

The chromosomal constitution of all these lines was followed from the first passage after explantation for 7 months. The number of polyploid mitoses varied initially from zero (primaries, untreated) to 40% (cells treated with $5 \mu\text{g ml}^{-1}$ cytochalasin B). The difference between treated and untreated cultures decreased however, and by the third week clear differences were no longer observed. In most of the 130 preparations examined, the percentage of polyploids was between 5 and 25. Quasi-diploid cells were in the majority but a stem line could not be identified¹².

When chromosomes were analysed for their banding pattern no real diploid metaphases could be found after the third week in all cases. The most common departures from normality were trisomies and monosomies and the number of translocations and other detectable structural aberrations, at up to five months, was usually no more than 2 or 3 per metaphase.

The conclusion we can draw from this set of experiments is that the karyotypal heterogeneity, known to be common in established lines¹³ begins soon after explantation, much sooner than suggested by earlier studies^{1,9,10}. Polyploidisation and the successive appearance of pseudo and quasi-diploid cells plays an important role in the evolution leading to establishment. This type of karyotype evolution may indeed be a rather general phenomenon since similar steps have been described *in vivo* during liver regeneration and in the bone marrow of adult and ageing hamsters^{12,14,15}.

H₁ and H₂ receptors in the histamine-induced accumulation of cyclic AMP in guinea pig brain slices

EVIDENCE has accumulated suggesting that several transmitters, as well as hormonal substances, mediate their actions on effector cells by an increase in the intracellular level of adenosine cyclic 3',5'-monophosphate (cyclic AMP).

Like other biogenic amines, histamine is able to stimulate the cyclic AMP-generating system in brain slices of different animal species². Moreover, this action of histamine on brain cells, like other cerebral actions (either electrophysiological³ or behavioural⁴), seems to be mediated by means of an interaction with specific receptors, as it is not blocked by adrenergic antagonists but prevented by classical antihistamines⁵. In peripheral tissues two classes of histamine receptors seem to be present as evidenced by specific antagonists or agonists. Ash and Schild⁶ have termed H₁ those blocked by classical antihistamines and H₂ the others, responsible, for example, for the gastric secretory effect of the amine. Since the discovery of specific antagonists and agonists of these H₂-receptors⁷, the existence of an H₂-mediated stimulation of adenylyl cyclase has been reported, as in fundic gastric mucosa of guinea pig⁸. We report the presence in brain of both classes of receptors involved in the histamine-induced accumulation of cyclic AMP.

Cyclic AMP accumulation was studied in an *in vitro* model, derived from that described⁹. Male Hartley guinea pigs (300 g) were killed by decapitation, their brain removed and slices of cerebral cortical gray matter (250 μ m thick)

Fig 1 Effect of histamine on cyclic AMP accumulation in guinea pig cortical slices. In the absence of added histamine 5.3 ± 0.3 pmol per mg protein of cyclic AMP were accumulated. The percentage of maximal accumulation of cyclic AMP, which represents $381 \pm 6\%$ of the basal level, is plotted as a function of histamine concentration. Mean \pm s.e.m. of five samples.

were rapidly prepared with a McIlwain tissue slicer. The slices were preincubated at 37°C for 30 min in the presence of 4 μ M adenine in a Krebs-Ringer bicarbonate medium (about 50 ml per g of slices), under a constant stream of a mixture of O₂:CO₂ (95:5) in a Dubnoff metabolic shaker. The slices were then pooled, washed twice with fresh medium and distributed in incubation tubes, about 7.5 mg of tissue per tube. After the addition of test substances, the tubes were gassed and capped, the incubations were continued at 37°C and terminated by homogenisation of the slices with a sonicator. Homogenates were heated at 95°C for 8 min, after centrifugation, the amount of cyclic AMP formed in the slices was measured in 10 μ l aliquots of the supernatant by the protein kinase binding method⁹. All test agents did not compete for the binding of cyclic AMP and the specificity of the assay was tested by incubation of selected samples with purified beef heart phosphodiesterase. Proteins were determined by the method of Lowry *et al.*¹⁰ with bovine serum albumin as standard.

Preliminary experiments indicated that the level of cyclic AMP in control slices was constant within at least 15 min of incubation, that the accumulation of cyclic AMP induced by 100 μ M histamine reached its maximal value after 10 min and that it remained at this level until 15 min. In further experiments, incubations were therefore continued for 10 min after the addition of the different test substances. Figure 1 shows the increased accumulation of cyclic AMP in cortical slices as a function of histamine concentration, the maximal effect was achieved by 50 μ M histamine and the half-maximal stimulation was obtained with 7 μ M histamine.

Two specific histamine antagonists were used to assess the characteristics of the cerebral receptors involved in the accumulation of cyclic AMP: mepyramine, a classical anti-histamine, which antagonises the activation of the H₁-receptors⁶, and metiamide, a new antagonist of the H₂-mediated histamine response¹¹. Figure 2 shows the effect of increasing concentrations of mepyramine or metiamide on the maximal accumulation of cyclic AMP induced by 50 μ M histamine. Both these agents were able to block the effect of histamine in a dose-dependent manner, although to a limited extent, that is, about 50%, in each case. The ID₅₀ (concentration of the drug giving 50% of its maximal inhibition) of mepyramine and metiamide were 0.06 μ M and 6 μ M, respectively, and the maximal antagonism was achieved by 1 μ M and 100 μ M.

Table 1 Effects of various effectors on cyclic AMP (pmol per mg protein) accumulation in guinea pig cortex slices

Agonist	Antagonist	Metiamide (100 μ M)	Mepyramine (1 μ M) + metiamide (100 μ M)
None	None	4 88 \pm 0 46*	4 58 \pm 0 26*
Histamine (50 μ M)	None	6 44 \pm 0 25†	
4-Methylhistamine (10 μ M)	Mepyramine (1 μ M)		
	(50 μ M)		
	(100 μ M)	4 99 \pm 0 29*	

* Not significantly different from controls

† Significantly different from controls, $P < 0.05$ Mean \pm s.e.m. of 3–8 experiments

Moreover, when the two antagonists were added together, the histamine-induced stimulation was completely abolished (Table 1). The effect of 4-methylhistamine, a H_2 -agonist devoid of any significant H_1 -mediated action⁷, was evaluated to further characterise the cerebral histamine receptors. 4-Methylhistamine stimulated the cyclic AMP accumulation in a dose-dependent manner, the response was not affected by mepyramine (1 μ M) but was completely abolished by metiamide (100 μ M) (Table 1).

Our results agree well with previous reports on histamine stimulation of cyclic AMP synthesis in the guinea pig cortex^{2,5,12}. The partial blockade of the response of histamine caused by mepyramine, a classical H_1 -antagonist, and metiamide, a new H_2 -antagonist, clearly suggests the involvement of both H_1 - and H_2 -receptors in the effect of histamine on the cyclic AMP generating system. Chasin *et al.*¹² have found that classical antihistamines were not able to block completely the effect of histamine. Further support for the presence of H_2 -receptors is provided by the fact that 4-methylhistamine, a specific H_2 -agonist, also stimulates cyclic AMP synthesis, an effect blocked by a H_2 -antagonist and not modified by a H_1 -antagonist. Moreover, the additive effects of the two antagonists suggest that the activation of one class of receptor does not affect the activation of the other.

The apparent 'dissociation constant' of histamine for the complex 'receptor-cyclic AMP generating system' is about 7 μ M and does not differ from that reported¹³ for human astrocytoma cells¹³, however, it is far higher than the dissociation constants of histamine for H_1 - and H_2 -receptors determined in tissues containing an homogeneous population

of each receptor (0.09 μ M (ref. 14) and 0.6 μ M (ref. 7), respectively). On the other hand, the ratio of ID_{50} of mepyramine and metiamide is of the same order of magnitude as the ratio of their dissociation constant in peripheral tissues^{6,11}. Therefore, our results suggest that the H_1 - and H_2 -receptors in the brain present common characteristics with those involved in the various actions of histamine in peripheral organs. The fact that we measured the histamine-induced cyclic AMP accumulation in slices, that is, the net result of a complex sequence of interactions, could explain the discrepancies in the dissociation constants for histamine.

In peripheral tissues containing the two classes, H_1 - and H_2 -receptors are often associated with dual effects of histamine, as in the superior cervical ganglion¹⁵. It is tempting, therefore, to speculate that in brain also, the increased intracellular level of cyclic AMP induced by histamine mediates dual effects according to the type of receptor activated by the amine. This could be the case if the different receptors are localised on different classes of brain cells. Consistent with this view is the histamine-induced accumulation of cyclic AMP in human astrocytoma cells¹³, suggesting the presence of histamine receptors on glial cells, whereas the same action on rat cortex synaptosomes¹⁶ suggests the presence of histamine receptors on nerve cells. On the other hand, the possibility that the same cerebral cell possesses the two types of receptors cannot be excluded, in this case the dual responses of the cell to histamine could reflect a localisation on different parts of the membrane and/or the triggering of cellular mechanisms which may occur with different time scales. In other respects, that at least one of the two types of receptors may be localised at cortical synapses is suggested by the recently demonstrated existence of an ascending histaminergic pathway in the medial forebrain bundle projecting into the whole telencephalon^{17,18}.

We thank Drs J. W. Black and M. Parsons for gifts of metiamide and 4-methylhistamine.

Experimental allergic encephalomyelitis: dissociation of neurological symptoms from lipid alterations in brain

EXPERIMENTAL allergic encephalomyelitis (EAE) is an autoimmune, paralytic disease that can be induced in experimental animals by injection of whole tissue from the central nervous system (CNS), or the purified myelin basic protein (PBP) homogenised in Freund's adjuvant. In some respects, it resembles certain human demyelinating diseases¹⁻³. Preferential changes occur in the metabolism of glycosphingolipids in the CNS³⁻⁶, some of which do not seem to be directly related to the presence of clinical symptoms⁴. In the guinea pig, changes in some of the myelin components seem to depend on the disease-inducing substance used. The cerebroside content of the CNS changes when this animal is sensitised with whole CNS, or with PBP and CNS lipids, but not when PBP alone is used as encephalitogen. The content of sulphatides changes the extent depending on the composition of the encephalitogenic preparation injected⁶. We report here that changes in the level of glycosphingolipids may arise in response to components other than the myelin basic protein and without the simultaneous occurrence of paralytic symptoms.

We have studied the brain lipid content of guinea pigs injected with mixtures of CNS lipids and non-encephalitogenic proteins. The latter preparations were chosen to include basic or non-basic proteins mixed or not with CNS lipids. There are some indications that the susceptibility to different CNS antigens may vary with the strain of animals used and this, in turn, may influence the magnitude of lipid alterations in EAE^{3,5,6}. As mixed bred animals from different sources were used in our studies, controls injected with encephalitogenic preparations were included to compare the lipid alterations found in the EAE animals with those obtained previously⁶.

Forty random bred, adult guinea pigs, of mixed colour and 500-900 g body weight, were randomly distributed in eight

groups and injected intradermally in each hind foot as in Table 1. The amounts of each lipid and PBP injected to animals of groups BP and BPL corresponded to the quantities of these components normally present in the amount of frozen rat spinal cord administered to group CNS. The quantity of PBP used is well in excess of the amount required to produce a high incidence of acute EAE in guinea pigs⁷. Thirteen days after injection the characteristic symptoms were present in all the animals injected with the encephalitogenic preparations (groups CNS, BP and BPL) whereas no neurological effects could be seen in the guinea pigs from groups CF, Ab, Py, AbL and PyL. All of the animals were killed by decapitation 14 days after the injection, the brain quickly removed and its lipid content analysed. Details of the preparation of PBP and CNS lipids and quantitative determinations employed were described previously⁶.

Table 1 shows that the differences in the contents of cerebroside, sulphatides and gangliosides in animals with paralytic symptoms were in general similar to those recently reported for groups CNS, BP and BPL (ref. 6). The changes for gangliosides were again not very significant. We confirmed our previous observations that the injection of PBP (group BP) induced a decrease in the content of sulphatides but not in cerebroside and that the inclusion of lipids in the injection mixture (group BPL) is necessary to induce alterations in the cerebroside levels and to lower significantly the sulphatide content⁶. The animals from groups Ab, Py, AbL and PyL did not differ in physical appearance from the controls (group CF), nor did albumin-injected animals (group Ab) differ significantly in any of the lipids studied. The injection of the basic protein poly-L-lysine (group Py) produced a pattern of alterations closely resembling that found in animals injected with PBP. The importance of lipids in the injection mixture for inducing the changes without the need for encephalitogenic protein and without the concomitant appearance of neurological effects is clearly indicated in groups AbL and PyL. In these groups the changes were very similar to those observed in animals from groups BPL and CNS. The whole mixture of lipids or only particular components could be necessary.

Since the method used for the determination of sulphatide may be altered by other lipids, and values for cerebroside have been obtained by difference⁶, a statistical comparison was made of the total hexose content of the monohexosyl ceramide fractions (cerebroside plus sulphatide). The results obtained

Table 1 Lipid content of the brain in EAE and non-EAE guinea pigs

Animals	Total lipids (mg per g wet weight)	Sulphatides (mg %)	Cerebroside (mg %)	Gangliosides (μ mol sialic acid %)	Total cholesterol (mg %)
Group CF*	81.94 ± 3.53	5.76 ± 0.25	14.86 ± 0.94	2.08 ± 0.13	19.71 ± 0.45
Percentage differences with respect to group CF					
EAE					
Group CNS	1.7	-54.7%	-45.9%	-23.6%	0.5
Group BP	6.0	-31.3%	-1.3	-20.7%	0.1
Group BPL	2.6	-50.7%	-52.2%	-18.8%	4.4
Non-EAE					
Group Ab	2.7	-17.0	4.8	1.9	1.9
Group AbL	6.0	-53.3%	-32.6%	-14.9	-3.6
Group Py	1.9	-42.5%	1.3	-16.3%	5.6
Group PyL	6.2	-66.3%	-25.4%	-22.1%	-1.1

Each group comprised five animals and the results are mean values \pm s.e.m. Animals were injected intradermally in each hind foot according to the following scheme: Group CF, 0.25 ml Freund's complete adjuvant (Difco Laboratories, Detroit, Michigan) emulsified with 10% water. Group CNS, the same as CF but including 35 mg of homogenised adult rat spinal cord. Groups BP, Ab and Py, the same as CF but including, respectively, 0.21 mg PBP from rat spinal cord, 0.21 mg bovine serum albumin (crystallised and lyophilised, Sigma, USA) or 0.21 mg poly-L-lysine (hydrobromide, Type I, molecular weight 41,000, Sigma, USA). Groups BPL, AbL and PyL, the same as groups BP, Ab or Py, respectively, plus a mixture of CNS lipids consisting of 0.16 mg sulphatides, 0.7 mg cerebroside, 0.85 mg cholesterol, gangliosides corresponding to 0.02 μ mol sialic acid, and phospholipids corresponding to 2.5 μ mol lipid phosphorus. Each of the preparations was sonicated for 3 min at 20 kHz in a Branson sonifier before injection.

*Individual lipids in group CF were expressed per 100 mg total lipids. In all the other groups the figures represent percentage differences between means, taking the values for group CF as 100%. P was calculated by Student's *t* test for non-correlated samples.

†Significant at $P < 0.02$

‡Significant at $P < 0.05$

§Significant at $P < 0.001$

in the different groups were consistent with the changes shown in Table 1. Thus, we found decreases of 48.4% ($P < 0.001$) in group CNS, 9.8% (not significant) in group BP, 51.8% ($P < 0.001$) in group BPL, 0.7% (not significant) in group Ab, 38.4% ($P < 0.02$) in group AbL, 11.1% (not significant) in group Py and 37.1% ($P < 0.02$) in group PyL, (control value 25.0 ± 1.2 μ mol glycolipid hexose per 100 mg of total lipid).

Our observations indicate that the presence of PBP in the injection mixture, necessary to induce the neurological disturbances observed in EAE, is not specifically required to induce the lipid alterations in the CNS. On this basis, EAE classically induced with whole CNS seems to be a composite result of different effects: the phenomena related to the paralytic symptoms elicited by the PBP, and the alterations induced by the lipidic components present in the CNS tissue, independent of clinical symptoms. Such differences between EAE induced by whole CNS and by PBP have already been observed. A demyelinating, or myelination inhibition, factor is present in serum of EAE animals sensitised with whole CNS but it is not consistently induced when PBP is used as encephalitogen^{8,9}. The antibody to cerebroside is responsible both for the disturbances in the sulphatide metabolism and the demyelination effects observed in cord tissue cultures exposed to EAE serum⁸. Thus, it seems likely that our observations *in vivo* may be caused by similar phenomena, as suggested⁶. Inoculation of rabbits with cerebroside, adjuvant and albumin resulted in perivascular infiltration in the spinal cord but not paralysis¹⁰; these findings seem to be closely related to those recently observed in EAE.

On the other hand, the surprising results obtained with poly-L-lysine suggest that the basic nature of the protein injected is closely related to changes in the content of anionic lipids. This should lead to a study of the effects of the injection of other basic, acidic and neutral proteins on the lipid composition of the CNS. Recent findings¹¹⁻¹⁴ regarding the highly specific interaction of the myelin basic protein molecule with negatively charged lipids such as sulphatides at the air-water interface are relevant. If such interactions and molecular arrangements are also occurring *in vivo* in the CNS, the alterations observed may be interpreted as the consequence of specific disruptive responses directed towards some of the interacting molecules or particular structural assemblies.

Marijuana, absinthe and the central nervous system

THERE are striking similarities between the psychological actions of the liqueur absinthe¹ and the experiences frequently reported by users of marijuana². We have therefore compared the properties of thujone and tetrahydrocannabinol (THC), which are believed to be the active principles of *Artemisia absinthium* and *Cannabis sativa*, respectively. Both substances are terpenoid, derived from the essential oils absinthol and cannabiol, and are formed by similar biosynthetic mechanisms^{3,4}.

The effects of absinthe have been known since the last century, but thujone has been conspicuously absent from recent lists of psychotropic plant products. It has been traditionally grouped with two $C_{10}H_{16}O$ isomers, camphor and menthol⁵, and classified as a convulsant poison. The molecular geometry of these three compounds is so different, however, that it is difficult to believe that, at low doses, they interact specifically with the same pharmacological receptors. At large doses, it is always possible that they exert similar, less specific actions by virtue of common physicochemical properties.

Thujone and THC have similar molecular geometry and similar functional groups available for metabolism. This close geometrical resemblance is illustrated in Fig. 1, in which the bonds common to both molecules are drawn as bold lines. The similarities include the gem-dimethyl groups at C₈, the C₇ methyl groups, the bonds connecting carbons 8, 4, 3, 2 and 1 of THC and 8, 5, 4, 3 and 2 of thujone, the α hydrogen at C₄ in THC and the cyclopropyl 5-6 bond of thujone and the 4-5 bond in THC and the 1-5 bond in thujone. Finally, although there is

Fig. 1 Structural formulae of thujone-enol (a) and $\Delta^{1,6}$ -THC (b). Bonds common to both molecules are drawn as bold lines. X indicates the site of the receptor with which the oxygen of the thujone molecule or the hydroxyl group of the THC molecule may react. See text for details.

Fig 2 Products of metabolism of $\Delta^{1,2}$ -THC (a) and $\Delta^{1,6}$ -THC (b)

no direct correspondence between the oxygen of the thujone molecule and the hydroxyl group of THC, it seems possible that both react with a common site of a pharmacological receptor, such as that indicated by X in Fig 1, without changing the orientation or relative position of either molecule

These oxygen atoms are likely to be the principal pharmacological binding sites because the primary metabolites from $\Delta^{1,2}$ -THC (ref 6) and $\Delta^{1,6}$ -THC (ref 7), both of which are physiologically active, are products of oxidation at C_7 (Fig 2). Indeed, these metabolites have been suggested as the actual psychotomimetic agents in marijuana⁷

The $\Delta^{2,3}$ -enolic form of thujone contains an allylic group at $C_{3,2,7}$ which is analogous to $C_{2,1,7}$ in $\Delta^{1,2}$ -THC, both systems should be available for similar oxidative reactions. In fact the electron-releasing ability of oxygen in the thujone enol should increase the rate of hydrogen removal at C_7 relative to a comparable reaction in THC (ref 8). That thujone can exist in the $\Delta^{2,3}$ -enol form is shown by its reaction with permanganate, a process known to involve enols⁹. Since the reaction affords an almost quantitative yield of the keto-acid¹⁰ shown in Fig 3 there is little doubt that the $\Delta^{2,3}$ -enol form is involved. Further, the existence of enols in biological systems is well documented¹¹

Fig 3 Permanganate oxidation of thujone by way of the $\Delta^{2,3}$ -enol

We propose therefore that both thujone and THC exert their psychotomimetic effects by interacting with a common receptor in the central nervous system. Topologically, this receptor should have a binding site for interaction with oxygen, a planar region to accommodate the allyl system, and pockets or cavities in which the alkyl and hydrogen substituents common to both drugs would fit. This hypothesis suggests new experimental approaches to study the pharmacology and toxicology of these and related compounds. A common mechanism of action for THC and thujone is also interesting from a historical and sociological point of view.

Decrease in 17β -oestradiol receptor in brain of ageing rats

We have shown^{1,2} that the administration of 17β -oestradiol to ovariectomised female rats induces acetylcholinesterase (AChE, EC 3.1.1.7) in the cerebral hemisphere and cerebellum, and that this induction decreases with increasing age. The greatest induction occurs in the immature rat, and there is no induction in the old. As 17β -oestradiol receptors are present in rat brain^{3,4}, we suggested that the impairment of AChE induction in the brain of old rats may be due to a decrease in the level of this receptor. This study was designed to test our hypothesis, and the data show for the first time that it may be correct.

Immature (7 week), adult (44 week) and old (108 week) female Wistar rats maintained in the rat colony were used. The rats of the three age groups were bilaterally ovariectomised and reared on tap water and standard diet for 21 d to ensure complete disappearance of oestradiol from the blood as described earlier^{1,2}. They were killed on day 22 and the cerebral hemispheres were removed to prepare a 10% homogenate (w/v) in Krebs-Ringer bicarbonate buffer, pH 7.4, containing 2.8 mmol glucose.

The procedure followed for characterising the oestradiol-receptor complex of the cytosol was adopted from that of Wong and Burton⁵ for the hydrocortisone-receptor in the nuclei of placenta. 3H -oestradiol (0.2 μ Ci) (Radiochemical Centre, Amersham) was added to 1.0 ml aliquots of homogenate and the samples were kept on ice for 30 min with occasional stirring. They were then incubated at 37°C for 10 min in a water bath shaker after which 5.0 ml of 1.5×10^{-3} M $MgCl_2$ were added to each. Then they were kept in ice for 15 min and centrifuged at 700g for 15 min at 0°C. The pellet was resuspended in an equal volume of $MgCl_2$ and centrifuged as before. Both the supernatants were pooled and centrifuged at 14,500g for 1 h. The supernatant thus obtained was fractionated through a 11 \times 180 mm column of Sephadex G-25-80 (Sigma) at 2°C using an elution buffer of 0.6 M KCl, 10 mmol Tris and 1.5 mmol EDTA, pH 8.0. Fractions (1.0 ml) were collected and a 0.1 ml aliquot of each fraction was applied on 2 \times 2 mm Whatman No. 1 filter and dipped in 12.0 ml of scintillation fluid (PPO, POPOP, 4.04 in 10.1 toluene). The radioactivity was counted in a Packard Tri-carb liquid scintillation spectrometer (Model 3003). The concentration of protein (μ g ml⁻¹) was measured according to the method of Sutherland *et al.*⁶. The averages of the data collected from four or five rats of each age are given in Fig 1.

Figure 1 shows a sharp peak and a high level of oestradiol-protein complex in the cytosol of the immature rat as compared to those of the adult and the old rat. The peak for the radioactivity corresponds to the protein peak. It is also noteworthy that the peak for the labelled-complex gets diffused in the adult and the old indicating a loss of specificity or affinity of the receptor protein of the cerebral hemisphere which binds to oestradiol.

So far, the only enzyme of the cerebral hemisphere which

Fig. 1 Elution profile of labelled protein (^3H -oestradiol-protein complex) (●) and total protein (○) of the cytosol of the cerebral hemisphere of, a, 7; b, 44 and, c, 108-week-old ovariectomised rats by Sephadex G-25-80 chromatography.

is known to be induced by 17β -oestradiol is AChE. Our data do not show directly that it is this 17β -oestradiol-protein complex which mediates the induction of AChE but the positive correlation between the degree of induction of AChE and of the level of 17β -oestradiol-protein complex is of great significance.

The lag period for the induction of tyrosine aminotransferase in the liver of the rat is known to increase with age⁷. We have shown that the induction of malate dehydrogenase⁸ and glutamine synthetase⁹ of the liver of rats by cortisone is impaired in old age. This impairment is similar to that of AChE of the brain^{1,2}.

These data show that the impaired induction of certain enzymes by steroid hormones in old age may be due to the depletion of specific receptor proteins in the cytosol of target cells. The receptor being a protein, its synthesis may be under the control of a unique gene whose expression may be regulated by a specific factor (for example, a hormone) that decreases after development. Also, the decrease in the level of a specific receptor with high affinity, and the possibility of the appearance of certain proteins having un-specific affinity for the hormone may account for the diffused nature of the receptor peak in older rats. The possibility, however, of the appearance of molecules which may repress specific genes of these enzymes in old age cannot be ruled out. This is consistent with the view that programmed changes in the activities of genes begin after fertilisation and continue throughout the life span^{10,11}. This may account for the sequential changes in the enzyme pattern as observed by us for cytoplasmic alanine aminotransferase of the liver of the rat during its life span (M.S.K. and S.K.P., unpublished). This may, in turn, account for differentiation, development and senescence of an organism.

The radioactivity was counted in Central Drug Research Institute, Lucknow. This research was supported by grants from the Nuffield Foundation, London, and the Indian Council of Medical Research, New Delhi, to M.S.K.

Interdigitated repeated sequences in bovine satellite DNA

MOST eukaryote genomes contain some highly repeated DNA sequences. DNA hybridisation kinetic studies indicate that the smallest repeating unit of highly repetitious DNA is around 300 base pairs¹ but direct sequence analysis of highly repeated DNA has demonstrated a simple basic repeating unit of 4–12 nucleotides^{2–5}. It has been postulated that the repeated sequences have been generated by successive replications of some primary simple sequence^{1,6,7}. The discrepancy between sequence data and kinetic analysis may be explained by noting that the rate of reassociation is a function of length⁸; this data is consistent with a model of internal heterogeneity in the repeated, simple DNA sequence units^{9,10}. Although the hybridisation and sequence analyses have been successful in establishing certain features of reiterated DNA, these methods are not well suited to detect and study infrequent but regularly repeated DNA sequences interdigitated within the dominant short repeating units. The existence and nature of such interdigitated repeats are important to our understanding of the mechanism by which repeated DNA is generated. We have used site-specific endonucleases (restriction enzymes) to show that mutational events within simple sequence DNA may have been coupled with cycles of discrete replications.

If a stretch of DNA were comprised of only a simple repeated sequence which contains the restriction endonuclease recognition site, it would be cleaved to fragments the size of the simple sequence. Conversely, if the simple sequence lacked the recognition site, it would be refractory to digestion. The results of digesting bovine DNA with the sequence-specific endonuclease isolated from *Haemophilus influenzae* Rd (endo R·Hind II+III)^{11,12} and analysing the digestion products by polyacrylamide gel electrophoresis have already been reported^{13–16}. This enzyme produces an expected continuous distribution of DNA fragments; superimposed on this distribution are at least twelve distinct, specific fragments ranging in size from 1.2×10^5 to 2×10^6 , and reiteration frequencies from 2,000 to 140,000 (in a previous report¹⁴ the smallest fragment, XII, was assigned a molecular weight of 7.5×10^4 ; our more recent data indicate it is 1.2×10^5). These twelve size classes of fragments could only be produced if the fragment termini containing the restriction site occurred at regularly spaced repeated intervals.

To ascertain whether there are additional interdigitated repeats besides those detected by the *Hind* digestions, bovine DNA was hydrolysed with endo R·Hae (the restriction enzyme from *Haemophilus aegyptius*¹⁷). Approximately 30 discrete bands were produced (Fig. 1, third lane). These fragments were generally smaller than those observed in a *Hind* digestion (Fig. 1, first lane). Most of the low molecular weight *Hae* fragments (Fig. 1, region 27–33) increased in size progressively by steps of approximately 10 base pairs up to a fragment length of about 100 base pairs. This step increase is in the size range of the simple repeating sequences found in other organisms^{2–5}. Although the digestion profile in the region of the larger fragments becomes considerably more complex, it is tempting to extrapolate that incremental size increases are by some variable multiple of a 10 base repeat.

- The relationship between the two sets of fragments generated by *Hind* and *Hae* was determined. Figure 1 (first, second and third lanes) shows a comparison of the digestion profile produced by a *Hind* plus *Hae* digestion with the profiles produced by each enzyme alone. This comparison showed that all of the *Hind* fragments were abolished by *Hae*.

To determine whether the *Hae* fragments are contained within the *Hind* fragments, preparative quantities of several specific *Hind* fragments were eluted from gels¹² and analysed after secondary digestion with *Hae* (Fig. 1). One obvious aspect of these results is that the sum of the molecular weights of the *Hae* fragments approximately equals the molecular weight of their respective parental *Hind* fragments. But, in the case of *Hind* fragments V and VIII the molecular weights of the derived *Hae* fragments add up to twice that of their respective parents, suggesting that *Hind* V and VIII are each comprised of two fragments. Cross contamination between *Hind* fragments can be ruled out as an explanation for this observation, since control experiments in which *Hind* fragments were re-electrophoresed on gels, indicated this to be less than 10%. Similarly, the sum of the *Hae* fragments does not equal the molecular weight

of *Hind* fragment III unless *Hae* fragment 6 is added twice as suggested by its relative intensity. Thus, it is concluded that in each case the *Hae* fragments are comprised of the same nucleotide sequences as their respective *Hind* fragment.

A second point is that a number of the *Hae* bands are common to several different *Hind* fragments (in this sense 'common' refers to fragments with the same electrophoretic mobility). For example, many of the low molecular weight *Hae* fragments in the region 19 to 30 inclusive are common to *Hind* fragments IV, V, VI+VII, and VIII (Fig. 1). Similarly, *Hae* fragments 19 and 20 are common to *Hind* fragments II, III, V, VIII, and IX, and *Hae* fragment 16 is common to *Hind* fragments V, VI+VII, and VIII, and there are other cases. These instances of the same *Hae* fragment occurring within several different *Hind* fragments suggest considerable internal sequence similarity among some of the *Hind* fragments.

The juxtaposition of individual fragments can be discerned by identifying DNA regions containing a *Hind* site adjacent to a *Hae* site. Such a configuration will yield fragments not shared by the *Hind*, *Hae*, and combined *Hind* plus *Hae* digestion profiles. One such overlap has been identified in *Hind* fragment XII by virtue of fragments 24

Fig. 1 *Hae* cleavage products of repeated *Hind* fragments in bovine DNA. The first three lanes are digests of total bovine DNA: first, *Hind* alone; second, *Hind*+*Hae*; third, *Hae* alone. Molecular weights were determined by coelectrophoresis with *Hind* fragments of $\Phi 80h$ DNA¹⁷. The remaining lanes are secondary digests prepared as follows. Total bovine DNA was hydrolysed with *Hind* and fractionated by electrophoresis on preparative 2% acrylamide-0.5% agarose slab gels at 4°C and 200 V (ref. 14). Individual bands were cut from the gel. The DNA was electrophoretically eluted and after concentration and dialysis was hydrolysed with *Hae*. Subsequent electrophoresis was on 4% acrylamide-0.5% agarose gels at 4°C and 200 V. The *Hind* fragments used as substrate for the secondary *Hae* digestion are given in Roman numerals at the top of each lane. Arabic numbers are assigned to the bands produced by hydrolysis with *Hind*+*Hae* or *Hae* alone. In some cases, faint *Hae* fragments occurring in *Hind* profiles are not labelled (for example, a *Hae* fragment in *Hind* fragment I corresponding to *Hae* fragment 3). There is a small amount ($\leq 10\%$) of cross contamination of *Hind* fragments in the preparative gels, and this is the most likely source of these faint bands. *Hind* fragments VI+VII have been presented together because they have not been adequately resolved on these gels. *Hind* fragment VII, however, is 15 times more abundant than *Hind* fragment VI¹¹; thus, *Hae* fragment 17 probably originates from *Hind* fragment VI.

Fig. 2 Determination of the partial order of *Hae* fragments within and overlapping *Hind* fragments VII and XII. Bovine DNA (1 mg) was hydrolysed with *Hae* and electrophoresed on a 4% acrylamide-0.5% agarose slab gel. The regions of the gel indicated by brackets were cut out, and the DNA was eluted as described in Fig. 1. DNA from the upper bracketed region and from the lower bracketed region, containing *Hae* unique fragments 11 and 19, respectively (see text), were each further hydrolysed with *Hind* and electrophoresed in 4% acrylamide-0.5% agarose (lanes *c* and *d*, respectively). Bovine DNA hydrolysed with *Hae* (lane *a*) and *Hind*+*Hae* (lane *b*) were included as controls. The numbers conform to the band labelling system utilised in Fig. 1. Lane *e* is an *EcoRI* hydrolysate of *Hind*+*Hae* digested bovine DNA. The molecular weights of the products were determined as indicated in Fig. 1. See text and Fig. 1 for further discussion.

and 29 (Fig. 1, lane XII) which are present only in the combined *Hind* plus *Hae* digest. Nearest neighbour information between *Hind* fragment XII and other *Hind* fragments can be detected by identifying those *Hae* fragments which on *Hind* digestion give rise to 24 or 29 (Fig. 3). *Hae*

fragment 11, which is not found in the combined *Hind* plus *Hae* digest, when subsequently digested with *Hind* yields fragments 13 and 29, in addition to undigested material (Fig. 2, lane *c*). Fragment 13 is found in the *Hae* digests of *Hind* fragments II, V, and VI+VII. Of these potential *Hind* fragments as neighbours to fragments XII, only fragment VII seems likely. This deduction is based on earlier evidence in which we determined that the buoyant density of sheared DNA containing *Hind* XII was the same as that of sheared DNA containing *Hind* fragment VII, and was of a significantly different density than that of sheared DNAs containing the other *Hind* fragments as nearest neighbour candidates¹⁴.

The neighbour on the other side of *Hind* fragment XII can be determined by similar reasoning. *Hae* fragment 19 which is not found in the combined *Hind* plus *Hae* digest, when subsequently digested with *Hind* yields fragments 24 and 27 (Fig. 2, lane *d*). As noted above, fragment 24 is unique to *Hind* fragment XII. Fragment 27 is found in *Hind* fragments IV, V, VI+VII and VIII. From the buoyant density data described above, fragment VII is the most likely candidate as the neighbour to XII. From this it is concluded that fragments VII and XII occur adjacent to one another, in an alternating tandem fashion. Other cases of overlapping regions which can be discerned by comparing the *Hind*, *Hae*, and combined *Hind* plus *Hae* digestion profiles will not be discussed here since they are less well resolved.

This conclusion that *Hind* fragments VII and XII alternate with each other is consistent with the observation of Botchan¹⁶ that purified bovine satellite I DNA, when digested with *Hind*, gives rise only to products corresponding to our fragments VII and XII. We have observed that the endo *R-EcoRI* restriction site¹⁸ discussed in the work of Botchan in fact occurs in *Hae* fragment VII-13, because it disappears in a combined *Hind* plus *Hae* plus *EcoRI* digest and gives rise to fragments of molecular weights 0.3×10^5 and 1.48×10^5 (Fig. 2, lane *e*, and Fig. 3). Similar conclusions have also been reached by P. Philippsen (personal communication) with the further finding that in addition to fragments 24 and 29 there is a very small *Hae* fragment which is produced from the centre of *Hind* XII.

Having obtained these patterns with *Hind* and *Hae*, it was of interest to ascertain whether any other restriction enzymes yielded equally dominant repeat patterns. To test this, a series of experiments was carried out in collaboration with Dr R. J. Roberts. A *Hind* plus *Hae* digest of bovine DNA was subjected to digestions with each of ten additional restriction endonucleases which were provided by Dr Roberts: *Hpa* I and II, *Hha* I, and *Hph* I (ref. 19);

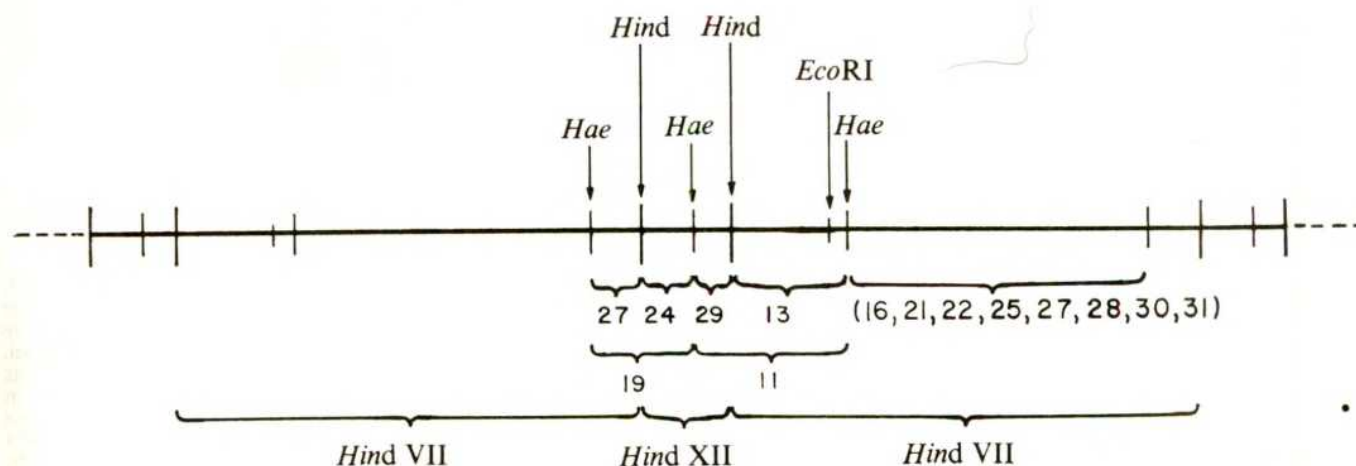

Fig. 3 Schematic representation of the arrangement of *Hind* fragments VII and XII and their internal *Hae* fragments. See the text and Figs 1 and 2 for further descriptions.

Alu I, isolated from *Arthrobacter luteus* (R. J. Roberts, unpublished); *Sma*, isolated from *Serratia marcescens* (C. Mulder, unpublished); *Hga* I, isolated from *H. gallinarum*²⁰; *Sal* I, isolated from *Streptomyces albus* G. (R. J. Roberts, unpublished); *Sac* I, isolated from *Streptomyces achromogenes* (R. J. Roberts, unpublished); and *Xan* I, isolated from *Xanthomonas amaranthicola* (R. J. Roberts, unpublished). The majority of the *Hind* plus *Hae* fragments were not abolished by these additional restriction enzymes, thus indicating that the repeats demonstrated by the rather frequent occurrence of the *Hae* cleavage site are quite sequence dependent (data not shown).

The internal DNA sequence within each of the fragments need not, *a priori*, contain reiterated DNA, but we have shown that most of the twelve *Hind* fragment size classes can be derived from positions in isopycnic gradients also known to contain satellite DNA (ref. 14). It has also been shown that at least two of the *Hind* fragments reanneal with the kinetics of a simple sequence¹⁶. Therefore, we postulate that the repeated *Hind* and *Hae* nuclease restriction sites differ only by one or a few bases from some primary repeating sequences. For example, in the hypothetical primary repeating decanucleotide sequence

a single transition in the eighth position could yield one of the two possible *Hind*_{II} nuclease recognition sequences¹¹,

(All twelve *Hind* fragments except for fragment VIII are bounded by two *Hind*_{II} sites; unpublished results.) Similarly, a single transition in the tenth position of this decanucleotide yields the *Hae* sequence

(K. Murray and R. Roberts, personal communication). A transversion in position 4 of the decanucleotide would yield the *Eco*RI recognition sequence.

(ref. 18) which occurs in fragment 13 (see Fig. 3).

The data presented in this report demonstrate the existence of different orders of interdigitated repeats within the satellite fraction of DNA. These results support the idea, advanced previously by others^{1,6,7}, that multiple rounds of replication, and/or unequal crossing over are separated by intervening mutational events.

Sequence analyses now in progress should serve to establish the precise relationship between the *Hind* and *Hae* nuclease recognition sites and the postulated primary simple repeat.

We are grateful to M. Botchan, P. Philippsen, and E. Southern for discussion of their unpublished data. This work was supported by grants from the US Public Health Service, a Bio-sciences support grant to S.A.G., and an American Cancer Society grant to A.L.

Super dense carotenoid spectra resolved in single cone oil droplets

CONE visual receptors in reptiles and birds contain brilliant yellow, orange or red oil droplets, 3-6 µm in diameter, through which light must pass before reaching the visual pigment. The possible role of these brightly coloured organelles in colour vision has been disputed¹⁻⁶. Their colours are thought to be caused by various carotenoids whose characteristically peaked absorption spectra in organic solvent extracts of whole retinas were first reported by Wald and Zussman⁷. In spite of this, subsequent workers have failed to identify the dramatic carotenoid spectra⁸ in individual oil droplets by direct methods of microspectrophotometry⁹⁻¹³. Instead, structureless cutoff absorbance curves reminiscent of commercial colour filters have been found to truncate at about one absorbance unit without any evidence of carotenoid spectral fine structure (Fig. 1).

It is not known why individual micromasurements do not substantiate the results of extraction. Neither is it understood, therefore, precisely how individual oil droplet colours are contrived. The flat-top and cutoff spectral character evident *in situ* might easily be accounted for by spectral overlap in various carotenoid mixtures. Alternatively, these properties might be a manifestation of instrumental limitations of microspectrophotometers¹⁴. Although our absorbance measurements on single oil droplets were done with some care, passing 1-2 µm diameter circular microbeams through their centres to reduce leakage of incident light around the sides, stray or scattered light might still dominate these measurements if the absorbance was very high¹⁴. Such artefacts could yield a plateau throughout the spectral region where true specimen density exceeds instrument capability.

To pursue this problem we initially improved our microspectrophotometer¹³ to record higher absorbances up to 2.7 but found the oil droplet spectra to plateau again at this new limit. Having achieved a practical limit for high-density microspectrophotometry, still without resolving spectral structure, we then turned to Lambert's law which suggests that absorbance might be reduced to measureably low values by reducing the optical pathlength. To accomplish this we squeezed oil droplets from freshly isolated retinas in a screw press under microscopic observation. We also air dried collections of oil droplets from distilled water to cause surface tension flattening. Still further thinning was achieved by exposure of air dried preparations to organic solvent vapours of hexane, pyridine, benzene or chloroform. We achieved only limited success with each method as we could only begin to see evidence of spectral fine structure. Moreover, the spectrum changed spontaneously on exposure to air and we could not achieve the quantitative results we now describe.

Retinas were removed from excised fresh turtle eyes (*Pseudemys scripta* or *Chelonia mydas*) in Ringer solution and were dropped into a small Petri dish of distilled water. After 30 min, a sediment of oil droplets released from lysed cells could be seen with a dissecting microscope. A drop of this sediment was sucked into a Pasteur pipette and transferred to a microscope

Fig 1 Spectra of individual cone oil droplets recorded directly in excised turtle retinas with a microspectrophotometer. Each spectrum shows a plateau near one absorbance unit. *a*, The swamp turtle, *Pseudemys*. From left to right, yellow, orange and red droplet spectra. *b*, The sea turtle, *Chelonia*. From left to right, yellow and orange droplet spectra.

slide. This was viewed at 650–1,000 \times magnification in an inverted microscope equipped with a Leitz micromanipulator. Individual oil droplets were then identified and their diameters measured. A 3–4 μ m tip micropipette attached to a pressure injection syringe was brought into contact with the oil droplet and a tiny drop of mineral oil (Squibb, USP C₈₋₁₂ hydrocarbon) expressed from the tip. As the two droplets fused, the pressure was quickly relieved and the pipette tip raised, leaving the new (20–50 μ m diameter) coalesced sphere attached to the glass slide with a swirling mixture of colour in its midst. Complete mixing, as evidenced by colour homogeneity, occurred within 10 s. The diameter of the new diluted droplet was measured and microspectrophotometry done using a 5 μ m microbeam passed through its centre. This produced resolved spectral structure in each case (Fig 2).

Using the conservation law, $C_1V_1 = C_2V_2$, and the Beer-Lambert law, $D = \epsilon cl$, where c is concentration, V is volume, D is optical density, ϵ is extinction coefficient, l is optical path-length and the subscripts 1 and 2 refer to the original and diluted droplet respectively, it is easy to see that the absorbance of pigment in the original droplet was

$$D_1 = D_2(R_2/R_1)^2 \quad (1)$$

if the droplets were spheres of radius R measured from their plan view. Histologically, the original droplets are spheres but as the diluted droplets are never seen in cross section, the above formula might not be applicable should the enlarged droplet flatten to become an ellipsoid or hemiellipsoid of revolution instead of a sphere. It can be shown, however, that these non-spherical forms yield self-cancelling effects on the dilution factor and pathlength leading to precisely the same formula as for spheres. Although it could be speculated that Beer's law might not apply at such high pigment concentration, we have evidence to the contrary, for the shape of the spectrum of the diluted pigment (Fig 2) at very long wavelength provides a satisfactory fit to the long wave part of the original spectrum (Fig 1) when scaled by the factor D_1/D_2 obtained from equation (1).

Thus, our experiments yield several conclusions (Fig 2, Table 1). Each pigment is exceedingly dense, indeed, such high recorded absorbances are unknown to us in any other cellular structure. The red and orange droplets of *Pseudemys* have the same spectral shape, that is, their pigments are identical. Their spectrum appears to match one of the extracts, that of astaxan-

thin^{7,8}, while that of the yellow droplet is similar to zeaxanthin or xanthophyll^{8,15}.

We conclude that in spite of similar composition the orange droplet cuts off at lower wavelength than the red simply because of its nearly tenfold lower concentration and optical density. The absorbance of the 6 μ m diameter red droplet, however, is 50–90 absorbance units. At peak, this droplet may transmit only 10^{-90} of light incident on it to the cone outer segment, that is, it cuts out 'completely' at peak. Preliminary results on the red droplet of birds also indicate extremely high optical density.

Table 1 Range of peak absorbance found in individual oil droplets by the method described in text

	R	O	Y
<i>Pseudemys</i>	50–90	6–9	12–18
<i>Chelonia</i>		4–7	3–4

R, red, O, orange, Y, yellow

Using its published extinction coefficient in hexane¹¹ it is possible to compute a concentration of about 1 M for astaxanthin in the *Pseudemys* red droplet. Using reasonable values for its partial molal volume, it can be concluded that astaxanthin itself occupies over half the space of the red oil droplet containing it. Indeed, if a red droplet is scratched with a micropipette, the material behaves like crayon or a viscous wax. Its failure to crystallise in these circumstances is probably consistent with the presence of a mixture of long chain *cis* and

Fig 2 Spectra of individual turtle oil droplets after enlargement and dilution with mineral oil. *a*, *Pseudemys*, three-fingered spectrum of yellow droplet (left hand trace) singly peaked spectrum of orange and red droplets (right hand trace). *b*, *Chelonia*, sharply fingered spectrum of yellow droplet (lower trace), orange droplet (upper trace).

trans isomers that retain a hindered fluidity or domain structure. In *Chelonia* a somewhat different picture emerges. No red droplets are present but both orange and yellow diluted droplets have a three-fingered fine structure. They are not quite a match, however, and we can only say that each droplet seems to contain a single pigment of high absorbance, though not as imposing as those of *Pseudemys*.

The oil droplet pigments of both turtle species are sufficiently dense to strongly alter the spectral distribution of light striking the photosensitive visual pigments. They must therefore play a role in colour vision and like the visual pigments themselves¹⁶, only a single pigment species is present in each cell.

We thank Dr Leo Lipetz who suggested that coloured oil droplets might contain immeasurably dense pigments. This work was supported by grants from the United States National Eye Institute and the United States National Institute for Neurological Diseases and Stroke.

Regulation of RNA polymerase II activity in a mutant rat myoblast cell line resistant to α amanitin

A MUTANT cell line, Ama102, resistant to the cytotoxic effects of α amanitin, the specific inhibitor of RNA polymerase II (refs 1 and 2), has been selected³ from cultures of Yaffe's⁴ rat skeletal muscle myoblast cell line, L₆, treated with mutagen. Ama102 cells have similar doubling times for growth in the absence or presence of 3 $\mu\text{g ml}^{-1}$ α amanitin whereas the Ama⁺ parent does not survive in this concentration of α amanitin. Studies *in vitro* (ref 3 and DS *et al*, manuscript in preparation) indicate that Ama102 cells possess an RNA polymerase II which retains about 30% of its activity in 0.1 $\mu\text{g ml}^{-1}$ α amanitin, a concentration sufficient to inactivate completely the Ama⁺ polymerase II. If α amanitin has a similar inhibitory action *in vivo* and *in vitro*, the normal growth of Ama102 cells in α amanitin coupled with the partial resistance of its RNA polymerase II activity to α amanitin *in vitro* seems paradoxical. Does the mutant Ama102 cell grow normally in α amanitin with only 30% of its normal RNA polymerase II active, or can the RNA polymerase II activity increase when the mutant is grown in α amanitin? The experiments reported here indicate that Ama102 cells can compensate for the partial inactivation of RNA polymerase II by α amanitin by increasing the RNA polymerase II activity.

The activity profile of the RNA polymerases obtained by DEAE-Sephadex chromatography of extracts of Ama102 cells grown for many generations in the absence of α amanitin

(Fig 1a) shows that polymerase II is partially resistant to 0.1 $\mu\text{g ml}^{-1}$ α amanitin. When these cells were grown for 4 d' in the presence of α amanitin (3 $\mu\text{g ml}^{-1}$) the polymerase II activity was completely resistant, representing a threefold increase in resistant activity (Fig 1b). There seemed to be no corresponding increase in polymerase I activity. The Ama102 cells responded to the exposure to α amanitin by modulating the activity of resistant polymerase II. This increased level of α amanitin-resistant RNA polymerase II activity was maintained even after 30 d of continuous growth in α amanitin (data not shown).

The α amanitin sensitivity of RNA polymerase I and II purified by DEAE-Sephadex chromatography from Ama⁺ and Ama102 cells grown with and without α amanitin was characterised further (Fig 2). RNA polymerase I from both wild type and mutant cells was not inhibited by up to 50 $\mu\text{g ml}^{-1}$ α amanitin, while the Ama⁺ RNA polymerase II was inhibited completely by 0.1 $\mu\text{g ml}^{-1}$. About 30% of the RNA polymerase II from Ama102 cells grown in the absence of α amanitin and all of it from Ama102 cells grown in 3 $\mu\text{g ml}^{-1}$ α amanitin was resistant to 0.1 $\mu\text{g ml}^{-1}$. This α amanitin-resistant RNA polymerase II activity was only inhibited by much larger concentrations of α amanitin (50% inhibition with 5 $\mu\text{g ml}^{-1}$). This α amanitin-resistant activity is distinguished from RNA

Fig 1 DEAE-Sephadex chromatography of RNA polymerase activities in α amanitin-resistant rat myoblast Ama102 grown in the absence and presence of α amanitin. Ama102 cells were grown in Dulbecco's modified Eagle's medium supplemented with 10% foetal calf serum (Gibco) at 37°C under 100% humidity in 5% CO₂-95% air. 10⁸ cells, washed once with citrate saline, were resuspended in TGMED (50 mM Tris-HCl (pH 7.9 at 22°C), 25% (v/v) glycerol, 5 mM MgCl₂, 0.1 mM EDTA and 1 mM dithiothreitol) containing 10⁻⁴ M phenylmethylsulphonylfluoride. Ammonium sulphate (4 M, pH 7.9) was added to a final concentration of 0.3 M, and the suspension was sonicated, diluted with 2 volumes of TGMED and centrifuged (30 min, 4°C, 125,000g). The supernatant was diluted with TGMED to 0.03 M in ammonium sulphate and used for chromatography on DEAE-Sephadex A-25 (0.9 × 12 cm), eluting with 10 ml of TGMED, 0.03 M in ammonium sulphate, then a 40 ml linear gradient, 0.03-0.5 M ammonium sulphate in TGMED. RNA polymerase activity was determined in column fractions (1 ml) by addition of 40 μl of enzyme solution to 80 μl of assay mixture⁹ which contained 2 μCi ³H-UTP (18-22 Ci mmol⁻¹). The reactions, 20 min at 30°C, were terminated by adding 0.01 ml 5% (w/v) sodium dodecylsulphate containing 0.25 M sodium pyrophosphate. 100 μl of the reaction mixture was spotted on 24 cm Whatman DE-81 filter disks and the filters were washed and counted². a, Cells grown in the absence of α amanitin, b, cells grown for 96 h in the presence of α amanitin (3 $\mu\text{g ml}^{-1}$). RNA polymerase activity was assayed in the absence of (○) and presence of (●) α amanitin (0.1 $\mu\text{g ml}^{-1}$).

polymerase III both by its elution from DEAE-Sephadex before the small amounts of polymerase III detected (Fig 1) and by its inhibition by concentrations of α amanitin lower than those reported to inhibit polymerase III⁵

We have examined the time course of the increase in α amanitin-resistant RNA polymerase II activity in Ama102 cells (Fig 3) Cells grown in the absence of drug for many generations were put into α amanitin ($3 \mu\text{g ml}^{-1}$) and the total

Fig 2 α Amanitin sensitivity of RNA polymerase activities from Ama102 and Ama⁺ cells purified on DEAE-Sephadex. Assay conditions were as described in the legend to Fig 1 except that each assay contained $5 \mu\text{Ci } ^3\text{H-UTP}$. \square , RNA polymerase I from Ama⁺, \blacksquare , RNA polymerase I from Ama102 grown for 96 h in α amanitin ($3 \mu\text{g ml}^{-1}$), \circ , RNA polymerase II from Ama⁺, \blacktriangle , RNA polymerase II from Ama102 cells grown in the absence of α amanitin, \bullet , RNA polymerase II from Ama102 cells grown for 96 h in α amanitin ($3 \mu\text{g ml}^{-1}$)

and α amanitin-resistant RNA polymerase activities in cell lysates were determined at various times under assay conditions where RNA polymerases I and III together accounted for no more than 17% of the total activity measured (D S *et al*, unpublished). Within the first 8 h there was a decline in the total specific activity (per mg total protein) of the RNA polymerase, probably resulting from the entry of α amanitin into the cells with consequent inhibition of RNA polymerase II activity. Within 16 h, however, the total RNA polymerase specific activity had increased to approximately its original value. This was entirely accounted for by an increase in α amanitin-resistant RNA polymerase activity. After 48 h of growth in α amanitin only α amanitin-resistant polymerase activity was detected in cell lysates. Removal of the α amanitin at 48 h led to a progressive decrease in the specific activity of α amanitin-resistant polymerase, the total RNA polymerase activity remaining constant. Fifty-six hours after removal of α amanitin, the levels of total and α amanitin-resistant RNA polymerase had returned to the prechallenge levels. The rapid change in the relative level of α amanitin-resistant RNA polymerase argues against the trivial possibility that these changes were due to selection of Ama^r and Ama^s subpopulations of cells within the Ama102 culture. Similar phenotypic regulation of RNA polymerase II activity has been observed in our laboratory in several other clones of independently isolated Ama^r myoblast mutants (M Crerar, S Andrews, and D S, unpublished).

These data indicate that RNA polymerase II activity in Ama102 is subject to regulation which is independent of that of the activity of RNA polymerase I. We suggest that RNA polymerase II synthesis in rat myoblasts is regulated autogenously as RNA polymerase synthesis seems to be in bacteria⁶. Based on experiments using *E. coli* *rif^r/if^s* merodiploids⁷ and *λif* infected *Escherichia coli*⁸ it has already been suggested

Fig 3 Changes with time of the RNA polymerase-specific activities in cell lysates of Ama102 cells grown in the presence and after removal of α amanitin ($3 \mu\text{g ml}^{-1}$). Ama102 cells, seeded in Falcon flasks (75 cm^2) at different densities to yield approximately 3×10^6 cells per flask when collected, were grown in the drug for various times up to 48 h. α Amanitin was removed from other flasks after 48 h, the cells were washed and fresh medium minus the drug was added. Ama102 cells were collected again at various times after removal of drug. The specific activities of RNA polymerase in the presence and absence of α amanitin ($0.1 \mu\text{g ml}^{-1}$) were determined in the cell lysates (3×10^6 cells suspended in 0.5 ml TGMED) prepared by four cycles of freezing and thawing (using liquid nitrogen and a 30°C water bath). The assay conditions were as described in Fig 1, except that each assay was made 0.4 M in ammonium sulphate to enhance the relative activity of RNA polymerase II compared with RNA polymerase I (D S *et al*, manuscript in preparation). Total protein was determined in these lysates by the method of Lowry *et al*¹⁰. The doubling time of Ama102 cells was 15 h in either the presence or absence of $3 \mu\text{g ml}^{-1}$ α amanitin. \circ , Total RNA polymerase activity, \bullet , α amanitin-resistant RNA polymerase activity. Downward arrow, addition of α amanitin, upward arrow, removal of α amanitin in the culture media.

that RNA polymerase may act as its own repressor. Our results suggest that this mode of gene regulation may extend to eukaryotes as well, although other mechanisms such as enzyme modification and end product feedback inhibition may regulate RNA polymerase II activity. A first requirement of this hypothesis of autogenous regulation will be the correlation of the increase in α amanitin-resistant polymerase II activity with an increase in *de novo* enzyme synthesis.

A blocked structure at the 5' terminus of mRNA from cytoplasmic polyhedrosis virus

METHYLATION of a specific nucleotide occurs at the initial stage of transcription of the double-stranded RNA genome in cytoplasmic polyhedrosis virus (CPV) in the presence of the methyl-group donor, S-adenosyl methionine (SAM)¹. Methylation of mRNA has been reported recently not only for other viruses^{2,3} but also for a mouse L-cell⁴. Since methylation seems to be coupled with the initiation of mRNA synthesis in CPV, the structure of the initiation (5') terminus of mRNA transcribed from CPV by the virus-containing RNA polymerase is of particular interest.

In the absence of SAM, single-stranded RNA transcribed from CPV *in vitro* has the terminal structure ppA-G-Y-. All ten kinds of mRNA, which correspond to the ten genome segments, have the same terminal structure⁵. The mRNA has the same sequence as the 5'-terminal-modified strand of the double-stranded RNA genome in CPV⁷ as well as in reovirus⁸. When SAM is added to the *in vitro* reaction mixture of CPV transcription, RNA synthesis is greatly stimulated⁷. The RNA synthesised in the presence of SAM is the same size as the RNA transcribed in the absence of SAM, but the former is methylated in the ribose moiety (probably the 2'-position) of an adenylic acid residue in the 5'-terminal region¹. We report the structural analysis of the 5'-terminal part of the RNA synthesised in the presence of SAM, showing that the 5'-terminal adenylic acid residue is methylated in the ribose moiety and, further, that the 5'-terminal phosphates are blocked by 7-methylguanylic acid.

Isolation of CPV and its RNA^{9,10}, construction of the system for *in vitro* RNA synthesis in the presence of SAM¹, and analytical methods for the oligonucleotides^{6,7}, have been published previously.

The mRNA synthesised from CPV in the absence of SAM carries α,β -diphosphates at the 5'-terminal adenosine⁶. Also in the presence of SAM, β -³²P-labelled ATP is incorporated into the newly synthesised mRNA. CPV mRNA doubly labelled with β -³²P-ATP and ³H-methyl SAM was prepared. When this was digested by various ribonucleases or alkali, both the radioactivities of ³²P and ³H were always found in one component in the DEAE-cellulose-urea column chromatography (details will be published elsewhere). This means that methylation occurs only at the 5'-terminus. These experiments suggest that the 5'-terminal sequence is ppAm-G-Y-. The terminal nucleotide (ppAm) obtained by *Penicillium* nuclease^{7,11} (see Fig. 3) was not, however, changed by the phosphomonoesterase treatment (Fig. 1a). Therefore, phosphate groups at the 5'-terminal nucleotide must be blocked by some unknown material, X, as XppAm.

This 5'-terminal material (XppAm) was then treated with venom phosphodiesterase. The products were separated by paper electrophoresis. As shown in Fig. 1b five components were detected by radioactivity, one of which (III) was non-degraded original material. Component II was identified as pAm (2'-O-methyladenosine-5'-phosphate). This contains a ³H-methyl group and moves with standard pAm, synthesised chemically¹², on paper chromatography. When this was digested with phosphomonoesterase, ³H-radioactivity was detected in 2'-O-methyladenosine. Component V is inorganic phosphate

carrying radioactivity (³²P). Component I at the origin (charge zero) was considered to be phosphorylated material X (Xp) because phosphomonoesterase treatment for this gave a material X, which moves to the cathode faster than any normal nucleoside at pH 3.5, indicating that it has a positive charge. From other experiments (details will be published elsewhere) the material X is labile in alkali, and contains a *cis*-diol. As candidates for X, SAM and 7-methylguanosine (m⁷G) were chromatographed and electrophoresed with ³H-methyl-X. In each case the radioactivity of ³H-X was simply superimposed on the ultraviolet-absorbing spot of 7-methylguanosine (examples are shown in Fig. 2). Therefore, X must be 7-methylguanosine.

In component I, the plus charge of X seems to be cancelled by the minus charge of a phosphate group at pH 3.5. As this phosphate did not carry radioactivity, this is not the β -³²P of the terminal 2'-O-methyladenylic acid. When α -³²P-labelled

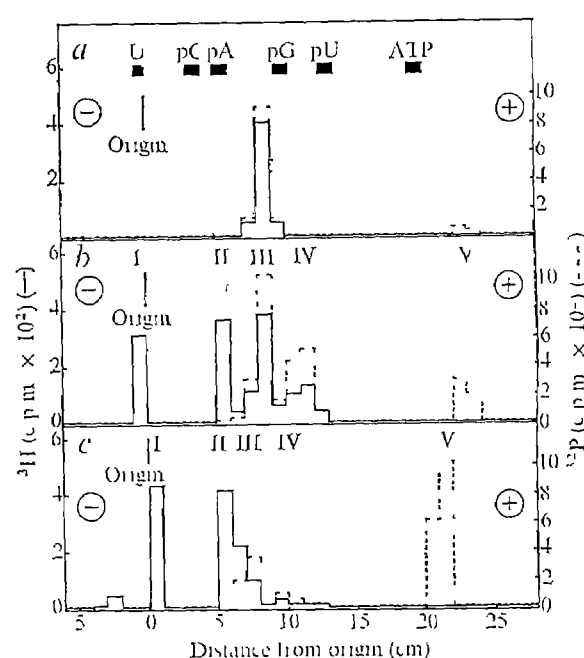

Fig. 1 Paper electrophoresis of the terminal oligonucleotide and its phosphodiesterase digest. *a*, Oligonucleotides obtained by *Penicillium* nuclease and phosphomonoesterase. CPV mRNA solution (100 μ l, ³H 60,000 c.p.m., ³²P 60,000 c.p.m.) was mixed with 5 μ l 0.1 M sodium acetate buffer (pH 6.0) and 20 μ l *Penicillium* nuclease solution, and incubated at 37°C for 90 min. The digest was spotted on Whatman 3MM paper and electrophoresed in pH 3.5 buffer (5% acetic acid, pH adjusted with morpholine), containing 5 mM EDTA, at 40 V cm^{-1} for 50 min in cooled hexane. After drying in a gentle air stream, the paper was cut into pieces (1 cm wide) and the radioactivity in each piece counted in 5 ml PPO- and POPOP-containing toluene. When the sample (20 μ l) was further mixed with 1 μ l phosphomonoesterase solution after adjusting pH to 8.0 with 1.0 M Tris-HCl buffer (pH 8.0) and incubated at 37°C for 30 min, a similar electrophoretogram was obtained. This means that the phosphate groups in the sample oligonucleotide are protected from phosphomonoesterase. *b*, Phosphodiesterase digest of *a*. The radioactive region in an electrophoretogram shown in *a* was extracted with 150 μ l distilled water. This sample (75 μ l) was mixed with 10 μ l 0.5 M phosphate buffer (pH 7.2), 1 μ l 1 M MgCl_2 , 2 μ l venom phosphodiesterase (Worthington, 7.5 mg ml^{-1}), and distilled water to total 200 μ l. The mixture was incubated at 37°C for 7 min. Paper electrophoresis as in *a*. *c*, Stronger digestion of *a* with phosphodiesterase. The same sample as the starting material in *b* was mixed with 20 μ l venom phosphodiesterase (15 times the concentration of *b*) and buffer containing MgCl_2 (same concentration as *b*) in 130 μ l total. The mixture was incubated at 37°C for 30 min. Paper electrophoresis was carried out at 36.4 V cm^{-1} for 50 min, otherwise as in *a*.

Fig 2 Identification of 7-methylguanosine linked to the terminal part of CPV mRNA. Fraction I in the phosphodiesterase digest of the terminal part of CPV mRNA, obtained from the *Penicillium* nuclease digest of the labelled mRNA (b), was eluted with distilled water, and digested with phosphomonoesterase under the same conditions as in Fig 1 a. The digest was spotted on Whatman 3MM paper and electrophoresed at 50 V cm^{-1} for 40 min in the same buffer as used in Fig 1 b. The digest was spotted on Whatman 3MM paper and developed with *n*-butanol-acetic acid- H_2O (5:1:4, V/V/V). As reference materials, SAM, S-adenosylhomocysteine (SAH), 7-methylguanosine, adenosine, cytidine, uridine, and the mixture of 5'-nucleotides (latter not shown) were run with the sample. Counting as in Fig 1.

guanosine-5'-triphosphate was added as a substrate, ^{32}P was incorporated into this component I. Therefore, component I is 7-methylguanosine-5'-phosphate (pm^7G). Component IV was considered to be the material X combined with two phosphate groups. By phosphomonoesterase treatment, ^{32}P was released as inorganic phosphate, together with ^3H -methyl-X. Thus component IV must be component I (Xp) further phosphorylated with ^{32}P phosphate which was incorporated from β - ^{32}P -ATP, that is, IV must be Xp^{32}P . Two phosphate groups would yield a minus charge for IV. Components III and IV in Fig 1b seem to remain because of incomplete hydrolysis by phosphodiesterase, as these components diminish when stronger conditions for hydrolysis are applied (Fig 1c). In the latter case there are three major components: I, pm^7G - ^3H -methyl, II, pAm - ^3H -methyl, and V, p^{32}P -phosphate.

Since the phosphate groups are blocked and protected from the phosphomonoesterase attack, 7-methylguanosine-5'-phosphate must be linked to the β -phosphate of ppAm through a pyrophosphate linkage. In fact pyrophosphatase treatment on the starting material yields 7-methylguanosine-5'-phosphate. Therefore, the starting 5'-terminal material has the structure $\text{m}^7\text{Gp}^5\text{pp}^5\text{Am}$ as shown in Fig 3. The number of phosphates between X and Am must be three, as the plus charge in m^7G was cancelled with one negative charge from phosphates

Fig 3 A proposed structure of the 5' terminal part of CPV mRNA and the enzyme-attacking sites. Radioactive components (\blacksquare , ^3H -methyl, \blacktriangle , ^{32}P). White arrow, attacking of *Penicillium* nuclease, black arrow, attacking of venom phosphodiesterase (after *Penicillium* nuclease digestion).

This consideration explains clearly the behaviour of the 5'-terminal material in DEAE-cellulose-urea column chromatography and in paper electrophoresis. Recently a similar blocked structure was reported for the 5'-terminus of low molecular weight nuclear RNAs from Novikoff hepatoma ascites cells¹³.

According to this analysis of the terminal nucleotide of CPV mRNA synthesised in the presence of SAM, the methylation occurs exactly at the initiation point (5'-terminus) of mRNA, as one of the genome duplex strands (ref 7 and K M and Y F, unpublished). In addition to the methylation of the ribose moiety of the terminal adenosine, 7-methylguanylic acid combines with the 5'-terminus of RNA by the 5'-5' pyrophosphate linkage. These modifications at the 5'-terminus of mRNA could play an important role in the initiation of mRNA synthesis and/or the function of mRNA. The blocked structure as well as the methylated 5'-terminal nucleotide of mRNA found here would be resistant to exonucleolytic attack, lengthening the life of mRNA. Alternatively, this modified structure may be necessary for completion of transcription, transportation and/or translation by forming a specific tertiary structure. Although the biological meaning of this modification of mRNA structure is not clear now, a similar modification has also been found in mRNA of vaccinia virus containing DNA as its genome¹⁴.

The authors thank Dr Kunitada Shimotohno for his helpful discussions, Prof James F. Crow for correcting the English, and Dr Akira Kunitaka for the supply of *Penicillium* nuclease. This work was partially supported by grants from the Ministry of Education of Japan.

Different effector cell types in antibody-dependent cell-mediated cytotoxicity

ANTIBODY-DEPENDENT cell-mediated cytotoxicity has been demonstrated *in vitro* using a number of continuously cultivated cell lines^{1,2} and nucleated erythrocytes³ as targets. Although the biological role of this cytotoxicity is not yet clear, it represents a potentially efficient cytotoxic mechanism and considerable interest has been shown in the characterisation of the effector cells.

The use of antibody-coated chicken erythrocytes (E-Ab) as targets has technical advantages and they have been widely used in assaying antibody-dependent effector cells. The report that effector cells in mouse spleen are monocyte-like⁴⁻⁶ was not easily reconciled with observations in our laboratory and elsewhere using cell line cells as targets. These authors assumed that the effector cells in mouse spleen active against E-Ab are the same as the effectors active against antibody coated cell line targets. It has been suggested that polymorphonuclear cells may participate in the reaction but even when these cells have been eliminated the possibility remains that more than one effector is involved. We have, therefore, made a direct comparison of the cells killing antibody-coated erythrocytes with those killing cell line cells coated with homologous antibody.

The results show that a population of effector cells highly active against antibody-coated erythrocytes has little or no activity against antibody-coated cell line cells.

The cytotoxicity assay towards antibody-coated chicken erythrocytes (E-Ab) was performed essentially as described by others^{3,6}. In addition two cell lines have been studied, the mouse mastocytoma P815 (M) and the human FL cell line (F)⁷. Each target was tested in the presence and absence of the appropriate antiserum at a dilution of 1:1,000, rabbit anti-E, rat anti-M and rat anti-human

Fig. 1 Treatment of spleen cells with carbonyl iron. Protein coating was carried out by suspending 200 mg sonicated carbonyl iron in 10 ml of medium containing 10% foetal calf serum and incubating on a roller at 37°C for 60 min. Uncoated particles were treated in serum free medium. 100 mg of iron was added to 5×10^7 cells in 1 ml in a tube and incubated at 37°C for 30 min. The unadhered cells were removed with the aid of a magnet and the iron particles resuspended in medium. These washings were recovered in the same way, pooled with the first cell suspension and adjusted to 5×10^6 ml⁻¹. C, Untreated control, Fe, uncoated iron particles, Pr, protein-coated iron particles. The percentage of cells recovered relative to the controls is shown at the top of the histograms. Clear blocks are M-Ab cytotoxicity, hatched blocks are E-Ab cytotoxicity.

Fig. 2 Fractionation on Ficoll-Trisil®. 5 ml of cell suspension was layered over 10 ml of Ficoll-Trisil and centrifuged for 10 minutes at 500g. Cells from the interface (I) and the pellet (P) were washed and suspended at 5×10^6 ml⁻¹. The percentage of total recovered cells in the pellet and interface is indicated at the top of the histograms. Total cell recovery was 80%. Clear blocks are M-Ab cytotoxicity, hatched block are E-Ab cytotoxicity.

erythrocyte. Except where stated the concentration of target cells was 10^7 ml⁻¹ and of effectors 5×10^6 ml⁻¹, the percentage ⁵¹Cr release was determined after mixing equal volumes of effectors and target cell suspensions and incubating for 4 h at 37°C. The percentage of cytotoxicity was calculated as (test-control)/(maximum-control) using as control the isotope release in the absence of antibody and the values for maximum release obtained by lysis of E in water (approximately 65%) and twice freezing and thawing the cell lines in hypotonic solution (approximately 80%). The data have been analysed by a multi-variable analysis of variance using logarithmic transformation of percentage ⁵¹Cr release. All the values presented as cytotoxicity represent killing significant at the 1% level.

In all the experiments the same preparation of effector cells was tested on the different targets under identical conditions. The results with the two cell lines were similar in each case except that the mastocytoma was more susceptible to killing.

In our hands mouse spleen cells show high activity against E-Ab but only low activity against antibody coated cell line cells. For example, BALB/c spleen cells tested at a ratio of 50:1 for 4 h on E-Ab, M-Ab and F-Ab gave 47%, 3% and no detectable cytotoxicity respectively, whereas under the same conditions Agus rat spleen cells gave 48%, 27% and 10% respectively. This conclusion is supported by other work (for example ref. 8) using antibody coated cell line cells and mouse spleen effectors where high ratios and a long incubation period (100:1, 16 h) were necessary for cytotoxicity. Other experiments (C. J. S., to be published) established that the difference between the two species was not the result of the source of antibody as similar results were obtained with mouse antibody. Because of this relative deficiency in mouse spleen we have used Agus rat spleen effectors in these experiments.

Treatment of spleen cells with carbonyl iron considerably reduces the activity towards E-Ab while only slightly reducing and sometimes enhancing the activity towards M-Ab. The cell recoveries suggested that this technique

was removing more than just the phagocytic cells. In an attempt to differentiate between phagocytosis and adherence the iron particles were first coated with protein. Examination under the microscope indicated that the coated particles were readily phagocytosed. Figure 1 shows an experiment in which uncoated and protein-coated iron particles were used. Uncoated iron shows a differential removal of activity towards E-Ab whereas protein-coated iron shows very little differential removal of activity towards E-Ab. The reason for this is not entirely clear, protein coated particles consistently remove fewer cells than uncoated particles, although coated particles seem to be readily phagocytosed. This suggests that these effector cells are being removed by adherence rather than phagocytosis. In an experiment using BALB/c spleen effectors, activity against E-Ab was decreased from 47% to 7% by uncoated carbonyl iron, while the activity towards M-Ab remained unchanged (35% to 33%). Thus, in both species, the activity towards E-Ab is more adherent than the activity towards M-Ab.

Figure 2 shows the distribution of activity after centrifugation on Ficoll-Triosil interface. Under these condi-

Fig 3 Fractionation on BSA gradient (modified from 10). 3.6×10^8 spleen cells were suspended in 1 ml of 35% BSA and placed in the bottom of a 10 ml centrifuge tube. A linear gradient from 35% to 20% BSA was formed over the cells. The tube was centrifuged in a swing out head (MSE Superspeed 65) at 20,000g for 30 min at 20°C. Approximately 1 ml fractions were collected from the bottom after puncturing the tube. The pellet was recovered with a Pasteur pipette. Cells were washed twice in serum free medium before counting and resuspending in medium at $5 \times 10^6 \text{ ml}^{-1}$. Cytotoxicity was determined after 5 h incubation. Cytotoxicity towards E-Ab is shown hatched, cytotoxicity towards F-Ab as clear blocks. Total cell recovery was 65% and the distribution is shown (●). Fractions 7 and 8 were pooled for the cytotoxicity assay. Unfractionated spleen control (C). The pellet (P) showed no activity against either cell line (arrow) but strong activity against E-Ab.

tions the cells recovered from the pellet are active against E-Ab with relatively little activity against M-Ab. The cells at the interface retain both activities.

In an attempt to make a better preparation of the lower density cells centrifugation was carried out at 1,000g. The cells recovered from the interface were then further purified by treatment with carbonyl iron. These cells gave 26.5% cytotoxicity with M-Ab and 75% with E-Ab.

These results indicate that the high density cells (pellet) active against E-Ab have little activity against M-Ab whereas the lower density cells with activity against M-Ab are less active against E-Ab. In each case it is not clear whether the residual activity against the other target cell is due to incomplete separation of the two types of effector.

In a further effort to improve the separation of the two types of effector cells we have investigated isopycnic centrifugation on different ranges of continuous bovine

serum albumin (BSA) gradients. Using a gradient from 35–20% BSA the cells recovered from the pellet show strong activity towards E-Ab with no detectable activity towards M-Ab or F-Ab. On the other hand, there is a population of cells with a peak at the middle of the gradient which is active towards all targets. Strong background killing of M in the absence of antibody was, however, also found in these fractions. The reasons for this are unclear (it may be caused by immune complexes in the BSA) but it made the calculations of cytotoxicity unreasonable and so only the data obtained with F-Ab are presented (Fig 3).

As the two cell lines we have used are quite different in origin and susceptibility to killing, it seems reasonable that other susceptible cell lines will be killed by the same population of effector cells. But the data obtained with E-Ab, at least with rodent spleen effectors, must be interpreted with caution and cannot necessarily be generalised to cell line targets.

Greenberg *et al* implied that treatment of mouse spleen with iron removed only cells with a phagocytic function, leaving non-phagocytic but adherent effector cells ("null cells"). It stems from our data and those of Dennert and Lennox¹¹ that the adherent properties of these cells can render them susceptible to almost total removal by iron, along with actively phagocytic cells. This effect may be responsible for the disagreement in the conclusions of various authors using E-Ab target cells^{6,11,12}.

In conclusion, rodent spleen contains two populations of antibody-dependent cytotoxic cells. One is a low density, non-adherent cell with activity towards cell line targets and chick erythrocytes. Mouse spleen is a relatively poor source of these cells compared with rat spleen. The second type of cell is a higher density, adherent cell. This is clearly the cell characterised by Greenberg *et al* as "null cells". These cells are present to a similar extent in both rat and mouse spleen, they are cytotoxic towards chick erythrocytes but not cell line targets.

We have avoided the suggested terminology (K-cells)¹³ because it is not clear whether it should be used to include both types of effector cell. We wish to thank Drs A C Allison and E M Lance for criticising the manuscript.

Age limitation of perceptual span

DIFFERENCES in speed of perception and performance between younger and older human adults sometimes increase proportionately with task difficulty, but sometimes remain constant. Gregory¹ has argued that the added time is adaptive and has shown how a constant component, such as age-associated

Fig. 1 Absolute thresholds of time exposure for correct identification of varying numbers of letters by different age groups ●, 20-30 age group, □, 40-50 age group, ▲, 60-70 age group

rise in 'noise' level, could result in a linear increase of decision time. Welford² suggests that the constant age effect occurs when signals are brief, whereas when perception is not limited, proportionate increases are manifested. We report here an example of a constant difference between age groups in absolute time thresholds followed by an abrupt change in a situation where signals are brief. The implication seems to be that two different deficiencies are operating, both of which could perhaps ultimately be attributed to 'noise'. Participants in the experiment were required to identify varying numbers of letters and the sudden increase in required time indicates a reduction in the visual perceptual span of older people.

A modified staircase method³ was used to determine the absolute time thresholds for correct reporting of 1, 2, 3, 4 and 5 upper case consonants. In estimating thresholds for more than 1 letter, correct order of report was required. Black stimuli (Letraset 719, 60-point spaced 10 mm centre to centre) were printed in the middle of a white card and displayed binocularly in a 3-channel tachistoscope with a dark pre- and post-exposure field. After every successful or unsuccessful trial the stimulus was replaced by a member of a set of 20 at each level of difficulty. Five male and five female volunteers in each of the age ranges 20-30, 40-50 and 60-70 were tested. To equate for age differences⁴, subjects in the young, middle and old age groups were dark adapted for 5, 7 and 10 min respectively, the experimental room having very low illumination (one 25-W red light bulb). Calculations are based on the mean of two estimates of threshold for each subject, order of presentation being 2, 3, 1, 4, 5, 3, 2, 4, 1 and 5 letters.

Results are given in Fig. 1 and show a dramatic increase in the exposure time required by the oldest group to identify 5 letters. Among that group there was only one exception to the very large time increment. Two members of the middle age group demonstrated a comparable increase, and there was one case in the oldest group with a similar increase at 4 letters. The youngest group had significantly lower thresholds than the two older groups for 1, 2 and 3 letters as well as a lower threshold than the oldest for 5 letters. The difference

between the middle and oldest group was only significant for 5 letters.

When stimuli were below threshold all age groups made most of their errors in the middle letters of a series. It is therefore unlikely that the limited perceptual span of the elderly is the result of poorer peripheral vision. For the same reason, output interference is contraindicated as the primary explanation, since such interference should lead to more frequent errors in the report of the last letter of a series. Nevertheless, a sensory memory storage deficit could be a major component in the reduction of perceptual span with age. This possibility is not excluded by the equivocal results of Abel's study⁵ using Sperling's⁶ partial report method, where exposure times of one half second were used. Many older participants in the present experiment made statements implying that they had seen a letter, but that it had disappeared before it could be identified. Similar comments have been reported from younger subjects in previous investigations⁷ and were made by members of younger age groups in a study we ran on time thresholds for more than five letters. The sudden increase in time we found with 5 letters among older people occurred at 6 or 7 letters in the young. Here, too, sensory storage is likely to be a major factor in limiting perceptual spans. Indeed, it would not be wrong to describe the perceptual span as a sensory memory span, since readout follows the disappearance of the stimulus and therefore must be formed from a lingering image.

We thank the Canadian National Research Council for support.

Errata

In the letter "Inhibition of adenylyl cyclase by an exotoxin of *Bacillus thuringiensis*" by D. G. Grahame-Smith, P. Isaac, D. J. Heal and R. P. M. Bond (*Nature*, **253**, 58, 1975) Figs 1 and 2 were transposed. The legends are correct as they stand.

In the letter "Sustained oscillations of acetylcholine during nerve stimulation" by Y. Dunant, P. Jirouneck, M. Israel, B. Lesbats and R. Manaranche (*Nature*, **252**, 485, 1974) the label on the abscissa of Fig. 1a should read 'Time (s)' and not as printed.

In the article "New observations of the angular diameter-redshift relation for radio sources" by A. Hewish, A. C. S. Redhead and P. J. Duffett-Smith (*Nature*, **252**, 657, 1974) there is a misprint on page 659. In line 18, 0.17" \pm 0.3" should read 0.17" \pm 0.03".

In the article "Two types of resistance to polyene antibiotics in *Candida albicans*" by C. C. Hsu-Chen and D. S. Feingold, (*Nature*, **251**, 656, 1974), the following corrections should be made to the legend of Table 2. In line 2, for CH₃COOH read MeOH, the expression in lines 4 and 5 should read [(c.p.m. of given phospholipid)/(total c.p.m. in phospholipid fraction)] \times 100, and not as printed.

matters arising

Simplification of palindromic telomere theory

CAVALIER-SMITH's motive in devising his palindromic model for telomeres¹ was to surmount the obstacle of the replication of the 3' end of a linear molecule of DNA (Fig 1). His palindromic end with related hairpin bend, however, makes the 3' end unnecessary and therefore, by the usual rules of natural selection, improvable.

This can be achieved by a slight modification of his original model (Fig 1). This has the attraction of not only being simpler, five steps replacing seven, but also of explaining the special property of telomeres which distinguishes them from any other end of a linear DNA molecule, namely a chromosome break their stability.

The essence of my model is that the self-paired telomeric palindrome is the normal condition, in G₁, G₂ and M. Then the phosphate backbone of the double helix is continuous through the telomere. Similarly, DNA replication

will proceed continuously through the telomere thus making the terminal RNA primer redundant.

This self-paired state is temporarily lost as the result of S and restored via denaturation. The endonuclease that nicks the end of the palindrome and allows the unfolding and refolding in the new configuration must be telomere specific, making it probable that all telomeres of one genome carry the same palindrome. Without this manoeuvre sister chromatids would remain attached end-to-end leading to non-disjunction at anaphase.

A philosophical attraction of my modification of the model is that the sister molecules (sister chromatids) participate equally in the process, in contrast with the original model in which one complete molecule is produced at once and the sister molecule is incomplete and has to go through a complex manoeuvre to correct itself. My model also requires one S phase, at the start. The original model starts and ends with DNA synthesis.

Finally, my model may be open to experimental confirmation. If the telomeric palindrome is long enough, the asymmetry between sister telomeres, one being old and one wholly new, might be detectable in autoradiographs of the first metaphase after labelling in S with ³H-thymidine. Wilson and Thomas report palindromes up to 12,000 nucleotides long². As there are only two telomeres per chromosome the possibility of recognising telomeric palindromes in DNA extracts would be like searching for the proverbial needle (or should we say hairpin?) in a haystack.

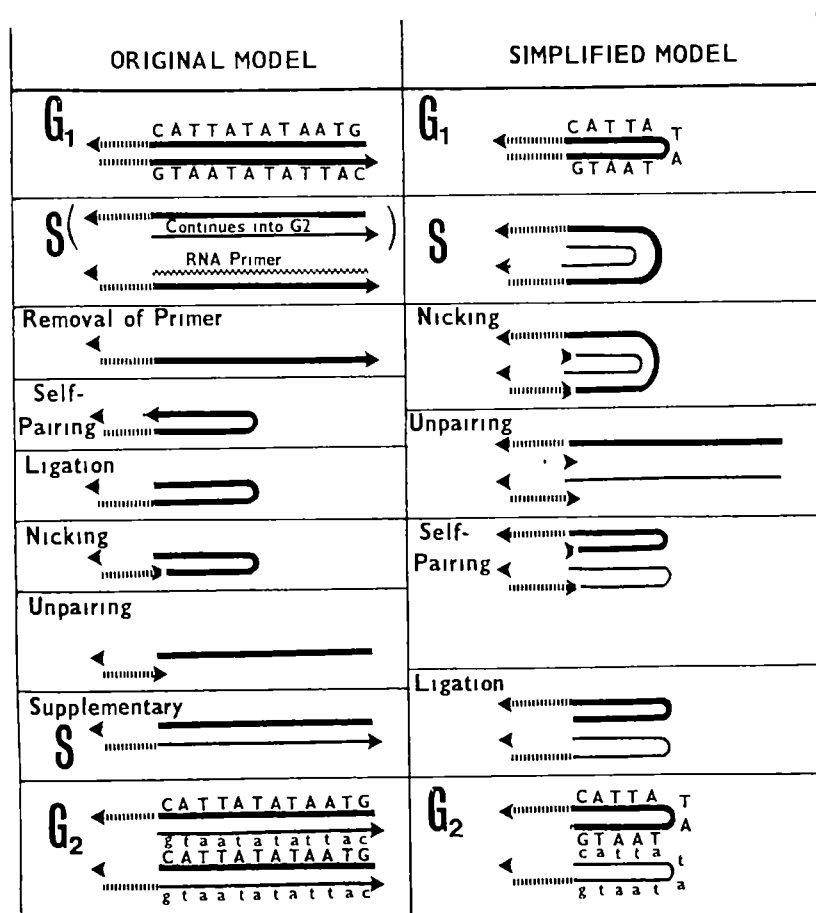

Fig 1 Two models for the replication of telomeres. —, Old DNA, —, new DNA, ---, RNA. The arrowheads indicate the 3' ends of the phosphate backbone. Capital letters nucleotides of old DNA. Small letters, new DNA. Entire line, the palindrome. Dotted line, the rest of the DNA molecule (of indefinite length).

- DR CAVALIER-SMITH REPLIES—I like Bate-man's modification of my model. It implies that a non-replicating eukaryote chromosome is a single, circular self-complementary polynucleotide chain, there are several ways this might be tested. In fact recent evidence indicates that vaccinia virus DNA may have this structure¹. Some other viruses do not, however, and an enzyme system has been isolated² from phage T7 which can cross-link the termini of some of them (T7, T3, T1 and λ) in the ways postulated in my original paper³.

This implies that even these phages have terminal palindromes, they may therefore be able to replicate according to my original model as well as (or instead of) Watson's concatomeric one. Another model involving a terminal palindrome has been independently proposed⁴ for the replication of linear mitochondrial DNA in *Tetrahymena*. But this postulates a palindrome only at one end and therefore requires a circular intermediate, and so seems implausible for eukaryote nuclear DNA.

Hepatocyte sialoglycoprotein

EVANS¹ reported that the plasma membrane enzyme nucleotide pyrophosphatase is located on the external face of the hepatocyte surface. Based on this result, Evans argues that proposals which suggest cell surface glycosyl transferases function in cell adhesion^{2,3} and in selective binding of asialo-glycoproteins⁴ are less tenable.

As nucleotide pyrophosphatase on the outer membrane surface rapidly cleaves nucleotide sugars and Roseman² has placed an important role for these glycosyl transferase substrates in his theory of cell adhesion, Evans says the proposed mechanism would not be possible. I wish, however, to re-emphasise our results which implicate liver plasma membrane galactosyl transferase in the binding of asialo-glycoproteins⁴. We suggest that this result modifies Roseman's original proposal to the extent that cells remain attached to one another by complexes between glycosyl trans-

ferases and their oligosaccharide products. Thus, the liver recognition of non-reducing terminal galactosyl residues on asialo-glycoproteins does not require any involvement of nucleotide sugars, as the active transferase seems to be galactosyl transferase for which the asialo-protein is a product, and not a substrate.

Evans' result suggests to us that another possible importance for nucleotide pyrophosphatase being localised on the exterior of hepatocytes is that this enzyme may catalyse degradation of external RNA. Clearly a cell must exclude foreign messenger RNA from its cytoplasmic environment, as such a molecule might function in protein synthesis resulting in the eventual transformation of that cell. Such a potent effect of RNA has already been shown to be operative for RNA tumour viruses. Naked RNA itself can be infective⁵, and the addition of other macromolecules which may complex with the RNA and thus protect it from enzymatic hydrolysis enhances infectivity⁶. Results have shown⁷⁻⁹ that liver plasma membrane degrades RNA, and inhibition of membrane phosphodiesterase (nucleotide pyrophosphatase) with EDTA diminishes this activity^{7,9}. A second, well-established marker enzyme for the plasma membrane is 5'-nucleotidase and it also has been shown to be on the outside surface of both liver¹⁰ and leukocyte¹¹ membranes. The 5'-nucleotide products of nucleotide pyrophosphatase would be substrates for 5'-nucleotidase, and indeed liver plasma membrane completely hydrolyses RNA to nucleosides plus inorganic phosphate⁷.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

DR EVANS REPLIES—Aronson is correct in pointing out that the binding of asialo-glycoproteins by a receptor, possibly a galactosyl transferase present in a liver plasma membrane fraction can occur without a requirement for sugar nucleotides. The involvement of sugar nucleotides in the transglycosylation reaction was postulated by Roseman to account for the de-adhesion process¹ and therefore their hydrolysis by the surface-located nucleotide pyrophosphatase would be a problem. Such proposals, however, must remain tentative until it is demonstrated more clearly that galactosyl and other sugar transferases are indigenous and functional components of the liver plasma membrane, and do not reflect contamination by Golgi membranes.

The plasma membrane fraction used by Aronson was shown to derive mainly from the liver sinusoidal surface² and to be contaminated by Golgi membranes as indicated by morphological markers and high activities of galactosyl and sialyl transferases^{3,4} that we have shown to be absent from the contiguous and bile canalicular face subfractions³. A fuller assessment of a possible role for cell surface galactosyl transferases and associated enzymes in the binding of serum components and in cell adhesion must await further analysis of the specific domains of the surface membrane and their interrelationships with Golgi membranes. Recently, the absence of cell surface galactosyl transferase in a number of cell lines was reported⁵, supporting the general conclusion that this enzyme does not play a role in cellular adhesion, cell recognition and contact inhibition.

reviews

Creative Malady. By George Pickering. Pp. 327+8 plates. (Unwin and Allan: London, 1974.) £5.25.

THE relationship between creativity and illness is one which stimulates the interest of most of us, particularly when an achievement is of the order of genius and seems to involve an impressive destructive action upon the subject's personal life. In this book Sir George Pickering, former Professor of Medicine at London University, attempts to elucidate this peculiar relationship by studying the lives of six famous people: Charles Darwin, Florence Nightingale, Mary Baker Eddy, Sigmund Freud, Marcel Proust and Elizabeth Barrett Browning.

The main hypothesis put forward by Sir George is that creative malady takes two quite distinct forms. In the first, exemplified by Darwin and Florence Nightingale, the illness serves a specific purpose: that of protecting the 'invalid' so that he or she can undertake the immense creative task undisturbed and unmolested. The second kind of creative illness can be observed in the lives of Freud, Proust and Mary Baker Eddy. In these cases productivity followed a period of "great turmoil and torment of mind" which were of sufficient degree to merit the term illness. Freud noted himself that he could not do creative work when he felt well and happy. The last subject in the book, Elizabeth Barrett Browning, unlike the others, showed no obvious connection in her life between creativity and illness.

Sir George gives most of his attention to the first of these types of illness as displayed by Darwin and Florence Nightingale. He has a rare gift for concise and vivid biography and these two lives make fascinating reading. Moreover, he is able to show clearly that the two subjects did indeed use their illnesses as a defensive barrier against forces which would have impinged on their work. (Both of them, for instance, became prostrated by palpitations and other symptoms in the face of intrusion by unwelcome friends, relations or public engagements.)

Creative Malady would, however, have been better if Sir George had focused throughout on that theme, for when he turns to other factors in creative illness he underestimates the complexity of the problem and is far less convincing. 'Creativity' and 'illness' are not simple and unambiguous con-

Genius and the mortal afflictions

"Creative genius arises, in a few rare people, out of an early despair of loving . . .

Therein lies the strength and ruthlessness of their drive.

Little wonder they are scarred or ill". Proust (pictured right) was only one of many so afflicted. Review by Peter Lomas

cepts and the two cannot be treated adequately as distinct entities. Take, for instance, Darwin's confessions about himself:

"I have said in one respect that my mind has changed during the last twenty or thirty years. Up to the age of thirty, or beyond it, poetry of many kinds, such as the words of Milton, Gray, Byron, Wordsworth, Coleridge, and Shelley, gave me great pleasure, and even as a schoolboy I took intense delight in Shakespeare, especially in the historical plays. I have also said that formerly pictures gave me considerable, and music very great, delight. But now for many years I cannot endure to read a line of poetry; I have tried lately to read Shakespeare, and found it so intolerably dull that it nauseated me. I have almost lost my taste for pictures or music.

This curious and lamentable loss of the higher aesthetic tastes is all the odder, as books on history, biographies, and travels (independently of any scientific facts which they may contain), and essays on all sorts of subjects interest me as much as ever they did. My mind seems to have become a kind of machine for grinding general laws out of large collections of facts, but why this should have caused the atrophy of that part of the brain alone, on which the higher tastes depend, I cannot conceive."

The impoverishment which Darwin describes could itself be considered either as a form of illness (in the sense of psychological disturbance) or as a state of mind liable to provoke manifest illness. How much impoverishment can a person take before becoming ill? To what extent was Darwin's neurosis caused by conflict between creative drive and the reluctance to pay the heavy price? And what is the origin of a drive so strong that it can, in many cases, wreak such personal havoc? Sir George does not really get to grips with questions of this kind and

that is because, in spite of his admiration for Freud, he places too little emphasis on early individual development. He comes closest to that in describing Proust's relationship with his mother.

Proust was 'in love' with his mother all his life and wrote *A la Recherche du Temps Perdu* only after her death, as if to fill a void. But I suspect that the real void began much earlier. Sir George quotes a moving passage from the great novel in which Proust describes his passionate dependence, as a child, on his mother's all-too-brief goodnight kiss. Sir George writes:

"Why then did Proust write a masterpiece while I have not? A difference of talent no doubt. Moreover, Proust was rich and never had to earn his living. While Proust was able to devote his whole talent to creating his book, I was leading an extremely busy life of practice, teaching, research and public affairs. But there is another great difference. While I was devoted to my mother, as he was to his, and while I had more need of her, since my father died when I was three, my *Recherche du Temps Perdu* would not have lingered on or indeed referred to any incident when my mother withheld the goodnight kiss. If she did so, I have no memory of it whatsoever."

That, I believe, is the crucial factor in an exceedingly complicated and little known phenomenon. Creative genius arises, in a few rare people, out of an early despair of loving. They create an alternative world as a substitute for the world they have lost. Therein lies the strength and ruthlessness of their drive. Little wonder they are scarred or ill.

Sir George may not have written a masterpiece. But he has given us a book which not only contributes to our understanding of creativity but also is a delight to read. □

Storage diseases

Enzyme Therapy in Lysosomal Storage Diseases. (Proceedings of the Workshop on Cell Biological and Enzymological Aspects of the Therapy of Lysosomal Storage Diseases, Leiden.) Edited by J. M. Tager, G. J. M. Hooghwinkel and W. Th. Daems. Pp. xi+308. (North Holland: Amsterdam and Oxford; American Elsevier: New York, 1974.) Dfl65; \$25.00.

THE identification of the lysosomal enzymes which are lacking in various human, genetically-controlled storage diseases, transformed the approach to this subject. Now that there is a large measure of agreement on the classification and manifestations of these diseases hope is rising that something might be done to ameliorate the conditions of those who suffer from the consequent physical abnormalities, mental retardation, pain and death. Most of the storage defects can be manifested in individual cultured cells which have enzymes missing and in which substrates consequently accumulate. Several of the defects can be identified in cultures of amnion cells, so that prenatal diagnosis is now feasible, which allows the possibility of induced abortion of homozygous children in affected families.

In April 1974 a workshop on the possibilities of enzyme replacement therapy was held in Leiden, and the papers presented were collected for publication in this volume. Many are concerned with the purification and further characterisation of the relevant enzymes and isoenzymes. Others are concerned with *in vitro* complementation, when cultured cells with different defects are fused to form heterokaryons or, remarkably, simply pick up enzymes from each other to attain phenotypically normal characteristics. Since the defect is in the lysosomal system, it may seem relatively easy to restore the missing enzyme, but replacement therapy presents serious difficulties. Liposomes have been used to introduce hydrolases into cells, where they can break down lysosomal contents in model systems. These can protect enzymes from inactivation by antibodies in the circulating blood.

Various attempts have been made to cure deficiency diseases by allotransplantation. In Fabry's disease accumulation of trihexosyl ceramide is often associated with deterioration of kidney function and, according to Desnick, kidney transplantation results in a fall in plasma trihexoside levels and the alleviation of painful crises. Although the missing enzyme, α -galactosidase A, is present in the urine, it is not demonstrable in blood, and the substrate is thought to be filtered from the blood and degraded in the kidney.

Enzymes administered by parenteral injection do not reach the central nervous system, so that a major problem will be to alleviate the effects of storage diseases there. If, however, levels of substrates in the blood could be reduced, there could be some beneficial effect.

The book's usefulness is increased by its rapid publication, made possible because the photo-offset process was used. The standard of reproduction of line illustrations is excellent and even that of half-tone illustrations is acceptable. I suspect that this will soon become the standard way to publish meeting reports.

A. C. Allison

Introducing physics

Solid State Physics. (The Manchester Physics Series.) By H. E. Hall. Pp. xviii+351. (Wiley: London and New York, September 1974.) \$15.00; £7.50.

THIS fourth book in the Manchester Physics Series is intended for use in undergraduate courses. The author has divided the text into two parts. In the first five chapters he presents a self contained, but elementary, introduction to the basic concepts of solid state physics, which should also be suitable for chemistry students. The early sections include topics such as crystal geometry, lattice vibrations, transport in semiconductors, free electron theory and magnetism. The remainder of the book is aimed towards honours physicists and contains chapters on band theory, X-ray and neutron scattering, thermal conductivity and Fermi surfaces. As a result of this division the formal constructs of reciprocal space and Brillouin zones do not appear until chapter six. The first chapter also flouts convention since the author attempts to explain why solids take up their various lattice structures rather than simply listing the possibilities. Indeed, the book begins with a detailed account of the quantum mechanics of covalent and ionic binding and the author follows this general line of argument throughout. The last few chapters on superconductivity, magnetic ordering and disordered solids are concise, but nevertheless, instructive. The section on the Fermi surface is, however, somewhat spoiled by the unwarranted amount of space (for a book of this kind) which is given to Overhauser's work on possible instabilities of the electron gas.

Each chapter has a useful set of problems associated with it, and answers are provided. I can recommend this as a good, if somewhat unusual, introductory text book. For a full honours course, however, one would probably require a little more experimental and theoretical detail than is contained here.

R. Evans

From metal to insulator

Metal-Insulator Transitions. By N. F. Mott. Pp. xvi+278. (Taylor and Francis: London, September 1974.) £6.50.

In the early days of quantum mechanics a simple model of metals was introduced in which all valence electrons were assumed to be free, or 'nearly' free, when a weak interaction with the static lattice of the positive ions was allowed for. The model predicted that in a perfect crystal the electron states would lie in bands and that each band could accommodate two electrons in every atom. Thus, materials with odd numbers of electrons in each atom, or with occupied and empty bands that overlap, would be good conductors. An insulator could only be changed into a metal (at least at zero temperature) by making its bands overlap. That outstanding prediction survived the test of time. In a real solid, however, the electrons interact with one another and also respond to lattice vibrations and the conditions under which a metal-insulator transition may occur depend to a large degree on the nature of those interactions. The main theme of Professor Sir Nevill Mott's book is to describe the effect of interactions between electrons in inducing magnetic moments and metal-insulator transitions. He reviews the present state of knowledge in the field from both theoretical and experimental standpoints.

The book is divided into six chapters. In the first, the concept of metal-insulator transition is developed within the framework of the model of non-interacting electrons in crystalline and non-crystalline media. The second chapter introduces electron-phonon interaction and exciton formation into the discussion of metal-insulator transition. Chapter 3 deals with the theory of localised magnetic moments in metals, magnetic ordering in non-metallic oxides and metallic ferromagnets, and also outlines the physics of the Kondo effect and its relevance to the main theme of the book.

Chapter 4 covers the metal-insulator transition resulting from correlation. This forms the hard core of the book and includes perhaps its best written passages. It begins with Professor Mott's original argument that at zero temperature a small number of free carriers can always form bound pairs through the long-range Coulomb potential, thereby producing an excitonic insulator. As a consequence, the corresponding metal-insulator transition involves discontinuity in the number of carriers.

Metal-insulator transition can, however, also take place without any reference to the long-range forces. The

Hubbard model, in which only intra-atomic correlation is included, predicts a continuous change in carrier concentration in the region of metal-insulator transition. This theory and its numerous extensions are discussed in some detail. The chapter also describes transitions in highly correlated metals and Wigner and Verwey transitions. The last two chapters apply the ideas of the previous chapter to metal-insulator transitions in transition metal compounds (V_2O_5 , Ti_2O_3 , VO_2 , NiS , and so on) and in disordered systems (doped semiconductors, metal-ammonia solutions).

It must be remembered that although some of the most important contributions to the theory of metal-insulator transition were made many years ago (N. F. Mott, *Proc. Phys. Soc.*, **A62**, 416; 1949) the field is still very much a new one and, as Professor Mott himself points out, there is, among theoretical physicists, no consensus to speak of. Under such circumstances Professor Mott's attempts to give a unified view, embracing a wide variety of experimental and theoretical material, must be highly praised. The book will be a welcome source of up-to-date information (a list of over 500 references to scientific papers and books is also included) to postgraduate researchers in solid state physics. **M. Jaros**

Sequences

Handbook of Nucleic Acid Sequences. By B. G. Barrell and B. F. C. Clark. Pp. 104. (Joynson-Bruvvers: Oxford, May 1974.) £4.40 cased; £2.50 looseleaf.

THIS handbook is essentially a comprehensive catalogue of most of the known RNA and DNA sequences so far published and, of necessity, the bulk of the listings refer to the 50 or so tRNA species which have been sequenced. Another attractive target for sequencers are the 5S ribosomal RNAs and although little can yet be said about their function, the primary structures of nine different species of this molecule have been established. Several other low molecule weight (4.5S-6S) RNAs are included as well as the sequences of RNA transcripts from some DNA phages.

A second major section lists all the known sequences from coliphage group I and group III RNAs, and the third section shows the current state of the art of the DNA sequencer and includes a synopsis of DNA restriction enzyme cleavage sites. One would anticipate that the field covered in this section will expand rapidly and it is to be hoped that arrangements are in hand for the regular updating of this collection. **J. Hindley**

Developmental Biology books

1975

Development of the Avian Embryo

A Behavioural and Physiological Study
B. M. FREEMAN and M. A. VINCE

December 1974; 380 pages; 15 pages of plates and 110 line illustrations; hardback: 412 115204; £10.10

This book considers the behavioural and physiological development of the avian embryo. After describing the physical conditions needed for development both in incubators and in the wild, the first part goes on to describe the major changes which occur in embryonic physique, posture and activity in the course of incubation. The second part discusses the physiological aspects of development in detail. The book is intended primarily for the research student and the established research worker.

Differentiation and Growth of Cells in Vertebrate Tissues

Edited by G. GOLDSPIK

December 1974; 334 pages; 109 tone and 25 line illustrations; hardback: 412 113902; £10.30

This book brings to the fore a relatively neglected part of developmental biology as far as textbooks are concerned; namely the development of the cells in different tissues of the body. There are seven specialised chapters, and each chapter is written by an expert in that field and an all-round picture is given of the biochemical physiology as well as the morphological events associated with the development of that particular tissue. The volume will prove invaluable to postgraduates and advanced undergraduates of biology and medicine.

Cellular Interactions in Animal Development

ELIZABETH M. DEUCHAR

February 1975; 308 pages; 12 pages of plates and 126 line illustrations; hardback: 412 130106; £6.50

This book provides a broad and critical survey of the many types of interaction that have been shown to take place between cells during the processes of development in animals.

CHAPMAN & HALL

The leaflet shown above describing these and related titles in detail is available from the publishers on request.

• Film review

Looking at ourselves before birth

A 25 day old embryo, with its connecting stalk and yolk sac.

To describe the development of a human being from ovum to newborn baby in just over half an hour must inevitably mean an extensive compression of the available factual material. In *Ourselves Before Birth* (Macmillan Educational Films) the precis is unfortunately uneven. Ovulation, fertilisation, implantation and the early formation of tissue of a human embryo are described in the first third of the film and the rest of the time is devoted to the growth of the foetus and the development of its blood supply. That imbalance is, however, a major flaw in an otherwise admirable presentation.

As an exposition on foetal growth the film must be one of the best ever made, and the graphics are excellent. But as an educational aid for the study of human embryology in the first few days of life it is disappointing. The men behind the film, Professor W. J. Hamilton and Professor T. W. Glenister, of the Univer-

sity of London, have tried to cram far too much complex information in the first part of the commentary without explaining the technical terms introduced. If the members of an audience already know the meanings of these terms then they have no need to watch the first ten minutes or so of what is a rather superficial treatment; if they do not understand them then they will not be enlightened by this film.

So, for me, the film fell between two stools. As an undoubtedly excellent account of later foetal development it is burdened by technicalities relating to early embryology, which are not explained adequately. There is, however, one marked exception. The implantation of the embryo is beautifully illustrated by the animation which alternates between two and three-dimensional views of the interior of the uterus and the inside of the blastocyst. This technique is most effective—why was it not maintained for perhaps another 10 minutes or so to surmount the hurdle of early tissue formation?

Being circumspect about plutonium

PLUTONIUM has emerged into the public gaze again in the past year or so not only because of disquieting reports of lax security at places where it is stored in the United States but also because of fears that the radiation safety standards for the substance, in particular its radioactive isotope plutonium-239, do not properly take account of its true toxicity. The former problem could affect many people very quickly—for example if a terrorist group were to steal sufficient plutonium to cobble up a crude bomb—but it admits of a simple solution through improvements in security. The toxicity question is, however, a thorny one, which has implications, in the first instance, for those who work with plutonium, although the matter is by no means irrelevant to the public at large.

Unfortunately for the clarification of the issue, some of the statistics that seem to point to an even higher toxicity than previously thought are not agreed upon—notably those pertaining to the nuclear fuel reprocessing plant of British Nuclear Fuels Limited at Windscale on the north-west coast of England, where five employees, ex-employees and pensioners of the company (which was hived off from the United Kingdom Atomic Energy Authority three years ago) have died of leukaemia, according to company records, in the 24 years the plant has been operating. On the basis of an average 'risk population' of about 3,000 during that period, the company says that the expected natural incidence of leukaemia would be at least four, an indistinguishably different number statistically. Those who take issue with British Nuclear Fuels say that 3,000 is an overestimate, perhaps by a factor of three or more, of those actually at risk and, furthermore, that radiation workers who leave that kind of work altogether are lost from the system of medical monitoring and checks that operates in the nuclear industry (a situation which in itself strongly suggests the need for some sort of national register of people who have ever been radiation workers, perhaps like the Transuranium Registry in the USA).

The statistics mentioned are at odds with each other to the extent that it has been argued that workers associated with plutonium are an order of magnitude more likely to contract leukaemia than people engaged in other occupations. Clearly, the only reasonable basis for new plutonium safety standards is a solid body of research and a careful analysis of the assumptions made in arriving at the present standards.

In a timely document published this week (*The Toxicity of Plutonium*, HMSO, 45p) the Medical Research Council (MRC), the body which advises the

government on radiation safety standards, taking into account the recommendations of the International Commission on Radiological Protection (ICRP), suggests that the part of the standard dealing with the inhalation of plutonium in insoluble form (for example, plutonium oxide, as used in the fuel of fast reactors) is too slack by a factor of five. The reasoning is based on the latest evidence available from the literature and on a reassessment of the 'critical organ' principle, which is still adopted for the plutonium standard by the ICRP, even though in the case of strontium-90 the commission has recognised that it is somewhat artificial. In essence, according to the principle, one regards a single organ or tissue as 'critical' in the sense that it is critically important in determining the MPAI (maximum permissible annual intake), at present set at 1 μ g on the basis that the lung is the critical organ. The MRC points out that several different organs—bone, liver and gut—are in fact "irradiated to a similar level of risk", and that in those circumstances a reduction in the MPAI would be required. The way the MRC's calculations come out, three of the MPAIs (those covering the ingestion of soluble and insoluble plutonium compounds and the inhalation of soluble ones) are about right, whereas the MPAI for inhalation of insoluble compounds is rather off-beam.

In its report, which contains a wealth of detail on all aspects of the toxicity of plutonium, the MRC also considers the 'hot particle' thesis, according to which the local irradiation of the lung by very active insoluble particles is markedly more carcinogenic than irradiation when the same activity is uniformly distributed. Although the report is unimpressed with the contention of Tamplin and Cochran that the MPAI for inhaled insoluble plutonium is 115,000 times too large for particles above a certain activity, this is a point which needs to be cleared up once and for all by experimentation on animals which are better models of human beings than beagle dogs. If work with, say, primates reveals a greater susceptibility to plutonium, then clearly the safety standards will have to be looked at again, and urgently.

No part of the MRC's report, of course, has a direct bearing on the way in which the standards are enforced or the steps taken to minimise accidents involving plutonium. In the UK the Nuclear Installations Inspectorate, together with the National Radiological Protection Board, is charged with that job, and the Royal Commission on Environmental Pollution is taking an overview of the whole situation in its examination of radiation hazards in general.

Vice-Chancellor Perry: "experience can be adapted"

Open for business

Britain's pioneering experiment in mass education, the Open University, has now developed to the point where it seems unlikely that any government will go so far as to close it down. This is a rather modest level of success—one would hardly be justified in saying that the Open University has in any sense 'come of age', even though it has produced its first graduates. But there was a real prospect that the incoming Conservative government of 1970 might have abandoned the experiment, and with higher education generally still in a parlous economic state the mere fact of the continued existence of the Open University is something to take note of. How might the bridgehead established by the Open University be used to best advantage in the coming years? And do conventional universities have something to learn from the Open University in terms of cost effectiveness?

—John Gribbin reports.

THE first lesson that might be learned by some academics is the combination of public relations ability and political awareness which the Open University staff seem to have. It's no secret that in the run up to the 1970 election the Open University's representatives took good care to lobby Margaret Thatcher, then in the Shadow Cabinet, and that this lobbying paid dividends when the Conservative government was elected, against all predictions, later that year. That might seem a wasteful diversion of effort which would, in an ideal world, be better spent on the development of the academic side of the university itself; but without that effort there might not

have been a university to develop.

Late in 1974, the Open University revealed to the public gaze an example of its business acumen with the establishment of a consultancy service "to help interested bodies overseas establish similar techniques and systems" to the teaching-at-a-distance techniques pioneered by the Open University itself. At that time, Sir Walter Perry, Vice-Chancellor of the Open University, commented that "in four years, the university has shown that distance teaching can be effectively deployed to solve pressing educational problems... There is now enough evidence to justify the belief that our experience can be successfully adapted to other environ-

ments and to other types of education", and a spokesman for the university stressed that although it has concentrated on teaching to degree level, "the Consultancy Service believes that similar techniques and systems can be applied to other kinds of education and training, especially life-long learning".

So the university is already looking well beyond the usual narrow confines of higher education establishments. This kind of facility could clearly be of great use in keeping teachers up to date, providing training in the law, or perhaps as a means of welfare and hygiene training. And these developments show clearly how the Open University might be made, if not to pay its own way entirely, at least to contribute substantially to its own running costs. The present marketing activities of the university are far from insignificant, as the table shows, although it must be born in mind that the "margin" mentioned there is not entirely profit—there are other overheads involved in running the marketing operation. The global scale of this marketing operation is also surprising to anyone used to thinking of the Open University as a British establishment; only just over 50% of present net sales are in the UK.

Perhaps the greatest "package" success of the Open University in the marketing field is the sale of complete courses to a few American colleges; in these packages books, course unit guides and broadcast material have been sold together and will be used just as they are in the Open University itself. This encourages speculation about the possibility of using modern communications facilities to centralise higher education to a great extent. If students in the USA can take what is in essence an Open University course (even, perhaps, an Open University degree) why should not the same facilities be used by UK universities? There is a powerful case to be made that, other considerations apart, the energy saving implicit in communicating a course to students, rather than transporting students to a course and housing them while they take the course, should alone lead to a major rethinking of our educational system. It is difficult to see that the interests of the country as a whole (or any country) would be less well served if the present scattering of scores of universities across the country were to be replaced by no more than half a dozen establishments organised along the lines of the Open University, perhaps on a regional basis. But that prospect is certainly not one which we are likely to see in the immediate future.

Any movement in that direction is bound to meet opposition from the academic establishment. But it is diffi-

grants, for example, is set to increase by almost \$40 million, to reach \$380 million.

As for the support of research and development in colleges and universities, an analysis provided by the Office of Management and Budget indicates that academic scientists will receive only about \$2,278 million of the total federal research budget proposed for next year. That represents an increase of only about \$52 million, which will not keep pace with inflation.

How will Congress treat the budget proposals? First, it should be noted that Congress this year has an entirely new mechanism for dealing with the federal budget. In the past, the Administration's budget proposals have been chewed over by individual appropriations committees in the House and the Senate, each of which is responsible for specific departments of the federal government. Since each committee operates independently, the process has been likened to each committee writing cheques without regard to what is in the bank.

This year, however, budget committees in the House and the Senate will establish an overall budget ceiling, and decide maximum amounts for each appropriations subcommittee to work to. Thus, for the first time, Congress will be able to compare directly the worthiness of programmes supported, for example, by NASA with those supported by the Department of Health, Education and Welfare.

Nevertheless, congress is unlikely to reduce budgets for such politically sensitive areas as energy research and development—although it may well re-order priorities within the energy research budget to favour environmental research, and solar energy and coal research, as against nuclear power. Similarly, the money available for biomedical research will probably be increased above the Administration's budget request.

Finally, it should be noted that two years ago, when Mr Nixon announced that he no longer required a full-time Science Adviser, the scientific community suffered a fit of apprehension that the federal science budget would immediately show a precipitous decline. But Dr H. Guyford Stever, who inherited some of the Science Adviser's responsibilities, noted last week that "some people have said that federal science has been drifting. I am pleased to note that it has been drifting upwards".

● During the past few years the National Institutes of Health (NIH) and its clients in the universities and medical schools have been awash with turmoil and indignation over the Administration's policies for supporting biomedical research. The budget un-

veiled this week will not help much in calming the troubled waters.

To begin with, the Administration has proposed cutting some \$315 million from the funds that Congress has already voted for the NIH for the 1975 fiscal year (which is now more than half over). Then, the budget proposed for the NIH in 1976 would reinstate only \$72 million of that cutback, to give the agency a total of \$1,805 million—\$279 million less than Congress has approved for 1975. To add insult to injury, the Administration is, naturally enough, claiming credit for proposing a \$72 million increase for NIH next year.

Another controversial item in the budget is that the Administration has signalled its intention to reduce expenditures on biomedical training. Attempts to do that in the past have invariably brought the medical schools to simmering point.

Although Congress will not go along with all the Administration's proposals for the NIH, another long and bitter battle can be anticipated and biomedical scientists will have to wait to see exactly how much money the federal government intends to spend on health research over the next 18 months.

As far as the NIH's budget for this year is concerned, the problem lies with an appropriations bill which Congress finally passed in December last year. Although the bill exceeded the funding levels recommended earlier by President Ford for a number of programmes, Ford signed the measure into law with the understanding that he would later ask Congress to revise it. His proposed revisions include reducing the total which Congress appropriated for the National Cancer Institute by \$128 million, and similarly taking \$38 million from the budget of the National Heart and Lung Institute and axing a total of \$190 million from the budgets of the other eight institutes. Furthermore, he has proposed slicing \$104 million from the funds that Congress has appropriated for programmes dealing with alcoholism, drug abuse and mental health.

Congress must, however, give its express approval within 45 days before any of those reductions can be made, and it is not likely to do so. For one thing, Congress raised up the NIH's budget in December in spite of an urgent plea from Ford to reduce it. And for another, during the past four years Congress has consistently appropriated much more money for biomedical research than the Administration has wanted to spend. It is conceivable, however, that, as a token gesture, Congress may shave a little off the NIH's budget for this year just to show willing to hold the line on federal expenditure.

To put the matter in perspective,

however, it should be noted that even with the proposed revisions in the NIH's 1975 budget, the agency would still have some \$265 million more to spend this year than last.

Thus, with budgets for the 1975 fiscal year far from settled, the Administration's proposals for next year are totally unreliable as a guide to what will actually be spent. Nevertheless, for what it is worth, the Administration has proposed a budget of \$605 million for the National Cancer Institute and \$293 million for the National Heart and Lung Institute. Those proposals would represent increases of \$36 million and \$7 million respectively over the revised budgets of the two agencies, neither of which is sufficient to keep pace with inflation, and both of which are well below the budgets approved by Congress for this year. A similar picture can be painted for all the other institutes of NIH.

As for biomedical training, the Administration has proposed that the NIH should allocate some \$124 million to training grants next year, compared with \$131 million this year. That proposal is unlikely, however, to find much sympathy either in Congress or in the medical schools, for last summer Congress passed a bill which authorised expenditures of some \$208 million a year on biomedical training. Congress approved that measure in response to previous attempts by the Administration to do away with the NIH's training programme entirely—attempts which threw the biomedical research community into apoplexy.

Thus, the federal government's support of health research is again marked by considerable confusion and is likely to become a source of yet more controversy. But two factors may help to clarify the situation in the next few months.

First, Senator Edward M. Kennedy has announced that he will carry out a thorough investigation of the federal government's biomedical research policies this year through his Senate Health Subcommittee. Although Kennedy has usually supported the biomedical research community's complaints against the government, he served notice in a speech at Yale University last month that the medical colleges have often failed to examine critically their most cherished programmes. And last week, President Ford finally appointed five members of a special commission, set up by an Act of Congress, which will undertake a review of the NIH's policies and programmes. The review will take 18 months and co-chairmen of the panel are Dr Franklin Murphy, chairman of the board of the *Los Angeles Times*, and Dr Robert Ebert of Harvard University. □

AN OPEN letter from the Soviet dissident Dr Andrei Sakharov to the head of KGB, Mr Y. V. Andropov, has just reached the West. The letter (shortened slightly in this version) reads as follows:

'On December 20, I received a letter from a mythical Russian Christian Party, which contained threats directed at my son-in-law, Efrem Yankelevich, and my one-year-old grandson.

The authors of the letter threaten to destroy them, if I continue my civic activity.

The content and whole tone of this letter make it obvious that it was composed by your officials with the aim of frightening me and forcing me to keep quiet.

The previous day I had received notification from the visa office that Yankelevich and his wife had been refused permission for a journey to the United States at the invitation of the President of the Massachusetts Institute of Technology.

Prior to this, their application had lain unanswered for a year and eight months. This coincidence cannot be accidental. I declare that the members of my family are hostages and are being used as a means of exerting pressure on me.

This has been confirmed again today. Two of your officials, who were tailing my son-in-law on the street, repeated word for word the same threats as before (adding some foul language) and demanding an end to my activity.

I demand an end to the harassment of me. I demand an end to the thugery, and assurances of security for my family.

Don't disgrace your department even more by threatening the lives of children in the way practised in Stalin's time.

In the present circumstances, for which your department bears the responsibility, I demand that permission be granted at once to Efrem Yankelevich, his wife Tanya Semyonova and their son to travel to the US for an unlimited period, but on Soviet passports so that they will have the right to return home when their security can once again be assured.

It is quite clear that they are hostages. The only way of ending this form of pressure on me is to give them visas at once.

I also demand immediate permission for my wife to travel to Italy for treatment (for her blindness).

I demand an end to the disconnecting of my international phone calls.

I demand an end to the judicial and extra-judicial persecution of my friends, including Sergei Kovalov, who was arrested on 27 December.

At the same time as sending you this letter I am making it generally available and appealing to the world public for its support and defence.'

Vera Rich adds:

With the enforced departure of Solzhenitsyn and Medvedev, the Academician Andrei Sakharov, has found himself in an increasingly exposed and lonely position as Russia's "voice of conscience". That the Soviet authorities would like to silence him was only too apparent from the vicious press campaign launched against him in September 1973. This having failed, the alternatives remaining are exile or

cation for emigration, began on a large scale in 1970-71, long before the top-level trade talks began. He says that the idea of limited emigration was decided at the Politbureau meetings held in preparation for the Twenty-fourth Party Congress which opened on March 26, 1971. (A large party of emigrants left on March 1st). It would seem, however, that the scale of the applications somewhat disconcerted the Soviet authorities, resulting in the imposition for a time of the "education tax" on Jewish intellectuals wishing to emigrate, together with the policy of harassment and general unpleasantness which persists to this day.

For the future, Polskii sees the continuation of "limited" emigration, but with increasing pressure on applicants, especially intellectuals. The five cities of Moscow, Leningrad, Kiev, Khar'kov and Minsk together account for 1,000,000 Jews—some 30% of the Jewish population of the Soviet Union, and virtually the entire Jewish intelligentsia. It is from these cities, that he expects emigration to be most difficult. Further, there is the concept of the "closed town", which has been mentioned in visa refusals—towns such as Sverdlovsk, from which, it appears, no emigration is to be permitted at all.

The current pressure on *refusniks*—dismissal from one's job, followed by prosecution for parasitism (being without visible means of support), may well account for a certain falling off in the number of applications. Nevertheless, says Polskii, the would-be emigrants are not entirely abandoning hope. While not actually putting in a visa application at present, a great number of them are careful to keep themselves provided with an up-to-date invitation from a relative in Israel, so as to be ready to apply the moment circumstances seem slightly more propitious.

● The Russian biologist and writer Vladimir Konstantinovich Bukovskii, at present serving a twelve-year prison sentence is a result of supplying Western psychiatrists with documents on the confinement of dissidents in mental institutions is reported to be dangerously ill. Although suffering from a heart condition related to rheumatism, a liver condition, and duodenal ulcers, Bukovskii is receiving no medical attention, and medicines sent to him by his mother have been returned. He is unable to digest the prison diet of salt herring, spratts and cabbage. In an appeal to Minister of the Interior Sholokov, sent on January 29, Nina Bukovskaya pointed out that her son "is being slowly murdered by being deprived of medical treatment and correct medical diet". To date, no reply to her appeal has been received.

Dissident voices

Polskii: expert *refusnik*

physical violence—directed not at himself but at his family—his wife, stepdaughter and her husband and baby.

● Physicist Viktor Polskii, who, after more than four years' delay, was finally allowed to leave the Soviet Union for Israel in December 1974, is perhaps one of the best authorities on the problems facing the "refusnik", since in his case, the customary harassment included a charge of dangerous driving, which could have carried a considerable prison sentence, but which, under the pressure of world opinion finally resulted in a fine of 100 roubles (£50).

Talking to *Nature* this week about Jewish emigration, and, in particular, the emigration of Jewish scientists from the Soviet Union as a result of the recent rejection of the trade agreement, Polskii stressed that in fact the policy of permitting limited emigration to Israel was begun before the Soviets entered upon their course of *detente* and trade agreements with the USA. Emigration, or rather, the appli-

cult to counter the argument that the Open University approach is simply more efficient at getting its message across to large numbers of people at reasonable cost. The BBC runs just one studio for Open University programmes, at Alexandra Palace in London, and each television programme takes about one day of studio time to produce. There is also an outside broadcast unit, and radio programmes seem to be produced with hardly any effort at all. With about 50 producers at Alexandra Palace who have some kind of science qualification and this rather shoe-string operation the unit produces programmes which are used for five years before being replaced. And although the initial cost may seem high, the cost per student over that period must compare favourably with the cost per student of conventional lectures, even before account is taken of sales of programmes to other educational establishments.

In addition, for many of the science programmes the demonstrations provided in the Open University programmes are far more elaborate than anything which could be put on, and expected to work, under the restrictions of an ordinary lecture theatre. Again, an experiment which could not be financed by dozens of colleagues separately each academic year is a viable proposition when it only has to be put on once for the benefit of five years' intake of a much larger student body.

Even so, the total cost of the Alexandra Palace operation is not excessive even by the standards of some 'ordinary' universities, and looks even more reasonable when set against typical government expenditure on education and science. The total number of people now working in this BBC department is just over 300, and in 1973-74 the cost of the operation (wages, transmissions, filming, graphics, scenery, rental, rates, lines, administration, travel, processing and presentation all included) was £2,090,000. About half of this goes on wages, £600,000 for the actual manufacture of radio and television programmes (including all repeat fees), £250,000 for transmitter running costs and some £200,000 for premises (including lighting, heating and so on).

With a smaller proportion of pupils in secondary schools in Britain now wanting to stay on to take A levels, and fewer of those who qualify at that level wanting to continue their education at university level immediately afterwards, perhaps the time has come to rethink our approach to higher education. The arguments in favour of a break between school and university are well known, and perhaps the Open University approach offers the best route by which

O.U. sales, nine months to Sep. '74.

to return to the academic system for prospective students who had, temporarily at least, had enough of studying and examinations by the time they had reached A-level standard. Without yet going so far as to reduce the number of conventional universities drastically, it does seem that flexibility in combining Open University education with more conventional courses could make the university system as a whole more efficient, both in terms of cost and in terms of providing the greatest flexibility of courses for the greatest number of students.

The longer courses offered by conventional establishments are obvious possibilities for this kind of development; the time is not yet ripe for the Open University to offer a complete medical course (if only because of the difficulties in obtaining practical experience) but is there any real reason why all prospective medical students should not complete a 'remote teaching' pre-medical course before moving on to practical work? It is also difficult to see why law could not prove an ideal

course for the Open University treatment, if only the lawyers could be persuaded to move into the last quarter of the twentieth century. And if pre-medical courses are feasible, why not 'pre-university' courses, either as an option or as an essential prerequisite for all students who wish to take degrees? Two years of such study, say, would provide an excellent opportunity both for the prospective degree student to decide if he really does want to return to the academic fold and for the university of his choice to decide if they really want him. It would not be unreasonable for the work involved in such a two-year period of study to count as one third of a degree course, or, following the present Open University practice, for the same workload to be spread over three or four years. Then, the period of residence at traditional university need only be two years, with considerable advantages for the efficient running of those establishments. As most universities that run 'mature student' schemes can report, there would probably be great advantages in terms of a reduction in the drop-out rate and an improvement in academic standards.

There are imperfections in such a scheme, as there are in most, and it would hit hard at some entrenched positions. But with the present problems of the educational system (which have recently led the Secretary of State for Education and Science, Reg Prentice, to order what has been called "an inquiry on the reluctant students") something must not only be done but must be seen to be done. In the absence of other constructive proposals, this possible line of development of the Open University must surely be considered seriously. □

international news

THE economic theories of John Maynard Keynes, coupled with the rising price of oil and the insatiable demands of the Pentagon, have helped produce promises of massive increases in federal support for science and technology in the United States. That, at least, is the prospect held out by President Ford's budget proposals for the 1976 fiscal year, which were unveiled earlier this week.

Taken at face value, the budget anticipates that the federal government will set aside some \$21,600 million for research and development next year—a huge increase amounting to \$2,822 million above the expected support for science and technology this year. At 15.5%, the increase would be more than enough to keep pace with inflation and if it is all spent, it would represent much the biggest increase in the science budget since the Second World War.

Unfortunately, however, the figures cannot be taken at face value and should be treated with extreme caution. For one thing, they will almost certainly be altered by Congress and, for another, the picture is not quite as rosy as it seems at first sight.

The President's budget is a remarkable document. Hundreds of pages of facts and figures richly laced with rhetoric, it is the product of thousands of man-years of effort and as such it is the most important policy document produced by the Administration each year.

The sharp increases which have been proposed for research and development next year owe their existence to three chief factors. The first is a massive increase in the budget proposed for military science and technology. The second is another sharp upturn in proposed

US budget: energy and the military do well

from Colin Norman, Washington

spending on energy research and development, and the third is the fact that President Ford, like his predecessor, has been converted to the Keynesian view that an expanding federal budget is a useful weapon against recession. Ford's total budget would entail outlays of \$350,000 million and a budget deficit of nearly \$52,000 million.

● A total of \$11,400 million has been proposed for military research and development, which represents a staggering increase of \$1,900 million over anticipated expenditures this year. The budget document is characteristically vague about how this increase in funds will be spent, but the Trident submarine, the B-1 strategic bomber and a project to provide "options for possible future deployment of a new intercontinental ballistic missile system" are among the items mentioned. In addition, a large increase has been proposed in a programme for testing nuclear weapons, the objective being to complete all large-scale testing before the introduction of a possible threshold test ban. Some \$201 million has been requested for nuclear testing.

The Department of Defense's share of the proposed military research and development budget amounts to some \$10,600 million, of which just over \$2,000 million is classed as research.

● Energy research and development is set to receive an increase of nearly

\$200 million, to reach a total of \$2,360 million next year. (See table).

Although nuclear fission would get the bulk of those proposed funds, and the liquid metal fast breeder reactor alone is set to receive nearly \$500 million, massive increases have been proposed for solar, geothermal, fusion and coal conversion technologies. The Energy Research and Development Administration have also announced plans to build a large Tokamak fast reactor at Princeton University in 1977. Designed to burn deuterium and tritium the machine would be the first fusion fast reactor in the US and it is expected to cost \$215 million.

● The Administration has proposed an increase of nearly \$300 million in the budget of the National Aeronautics and Space Administration, chiefly for the development of the Space Shuttle.

Simple addition shows that between them, those three areas carry off all but about \$480 million of the entire increase proposed for the federal science and technology budget. Some programmes have therefore been squeezed.

Biomedical research is one such area, and space research is another. No new space project will be started by NASA next year, and aside from development of the Shuttle the budget for most NASA activities will be held constant. Sufficient money has, however, been proposed to keep all existing space projects alive, and NASA has also been allowed to proceed with plans for a third in the series of Earth resources technology satellites.

Nevertheless, the overall picture for science and technology is remarkably bright. According to an analysis prepared by the Federal Council on Science and Technology, the budget would entail an increase of about 8% in expenditures on basic research, thereby reversing the trend of declining support of such activities which began in the early 1970s. Between 1970 and 1974, for example, federal outlays for basic research declined by 15% in purchasing power.

Another indicator of proposed support for basic research is the fact that the budget for the National Science Foundation (NSF) is set for a healthy increase. Overall, the Administration has proposed that the NSF's budget should increase by \$78.3 million next year, to reach a total of \$775.4 million. Some 83% of the NSF's budget is earmarked for support of basic research. The NSF's support through individual

Making money and influencing people

from Angela Croome

LAST week the UK National Research Development Corporation (NRDC) announced that it was putting slightly over £500,000 into the development of a 200-passenger sidewall hover-ferry, the Hovermarine 5 (HM5). This caused some raised eyebrows, as Hovermarine, managed by Britons with a factory at Southampton, is now an American-owned company and the NRDC is, as its name suggests, dedicated to the promotion of inventions and applications to the national benefit using government money.

The loan is not anomalous, however, though it is of more than average interest. The NRDC holds the key hovercraft patents and issues the licenses for using them worldwide, so that any expansion by their licensees (such as Hovermarine) brings cash flowing in to London. (The NRDC itself has made a profit for the last few years.) In fact under its new American-style management Hovermarine's craft are now more widely sold than any other hover-ferries in the world, with 30 HM2s operating in 14 different countries, and the business has consistently doubled each year since the 1969 takeover. The company has played down the "new technology" aspect of the product and has emphasised its solid commercial and environmental advantages—such as its high speed, low cost, wake-free passage and high manoeuvrability. Currently, Hovermarine is the only licensee for sidewall hovercraft. Sidewalls, which provide solid containment for the air cushion along the craft's long axis and, acting as twin keels, aid manoeuvrability, essentially economise on fuel and power compared with competitive craft such as the fully amphibious hovercraft, the motorboat and the hydrofoil. The HM2 cruises at 30 knots; the HM5 is expected to cruise at 45 knots. By putting up the most substantial sum it has spent on hovercraft for a number of years the NRDC is saying in unequivocal fashion that it is pinning much faith in the future of sidewall hovercraft as sheltered-water ferries and, by implication, approving the commercial and sales skills of its licensee every bit as much as its technical flair.

The NRDC has just passed its 25th anniversary and has also gained a new Managing Director, Bill Makinson; he is not new to the corporation, however, having worked there since the mid-1960s. Does the major new loan reflect a shift in policy with a change of team, or the fruit of a quarter of a century's experience in seeking out and fostering worthwhile innovations?

The Hovermarine 5: £500,000 development programme

On the occasion of the 25th anniversary and the announcement of the annual accounts, the NRDC revealed that it was being heavily underused and described efforts to rectify the position. It is entitled to borrow £50 million from the government for encouraging promising inventions and techniques. Only £21 million is at present in use. The board is concerned that the existence of the corporation, much less its role and method of operation, is scarcely known to the part of the population that could benefit from it. Government research establishments have provided a steady stream of ideas for NRDC sponsorship in the past. These are now being deflected to some degree, following the rearrangements resulting from the Rothschild customer-contractor principle. Only 2% of private inventions that reach the corporation are worth following up. Few small and medium businesses—a major untapped source of innovative concepts—seem to be aware of the NRDC's existence. Good ideas from the universities are even rarer and this is attributed again to ignorance of the existence of the corporation. The NRDC has over the past couple of years found that there is not only a total shrinkage of good proposals coming its way but that the balance is poor. It likes to keep a reasonable match between its nine groupings.

In the face of this surprising situation in a tight money market, the corporation has launched an advertising campaign to get its opportunities better known. It has also set aside £1 million specifically for investment in good ideas from the universities. There is no indication that either move has had much impact.

There are various criticisms that can be levelled at the NRDC's present mode of operation and which may well be bound up with its faceless image. Just how it runs, and on what basis decisions are reached, are obscure. Just how much interference it experiences or fears from government departments is an open question. For instance is it really likely that a proposal turned down by Science Research Council would be pursued by the NRDC—the Laithwaite 'magnetic river' project is a case in point. The corporation claims that Whitehall has never gibbed at one of its projects; but is that necessarily a matter for congratulations? The virtue of such a body is that it should provide a genuinely alternative option. There is a widespread sense that the corporation operates too much as a bank and insufficiently as a sponsor of research and development as its title suggests it should. It is free to encourage and invest beyond the development phase of bringing a good product to the market place, and it is now generally acknowledged that the major costs arise at the production and marketing stage. But there are few, if any, cases where the NRDC has helped over these final and most costly hurdles, and plenty of examples of products that have failed because of lack of capital or expertise at the end of the 'run'.

There is no lack of expertise, skill and sound judgment in NRDC. It just does not seem to make the most of itself and under present economic conditions there is surely more need of such a supporting body than there ever was. The stocktaking at the start of its second quarter century seems an excellent moment for reassessment and review. □

THE underlying purpose of the annual meeting of the American Association for the Advancement of Science (AAAS) is not all that easy to pin down. Partly an attempt to improve that ill-defined entity the public understanding of science, and partly a forum for exchanging views on a variety of social and political issues, it is, in the words of the retiring AAAS President, Roger Revelle, a "scientific smorgasbord". Whatever its *raison d'être*, the 141st such event took place last week in New York City and a good time was had by all.

The theme of the meeting was "Science and the Quality of Life", which was interpreted broadly enough to include a session on the emotional reactions of plants and a talk by Isaac Asimov on "The Science Fiction Writer as Prophet". Discussions concerning the health effects of pollutants, the energy crisis, world food shortages and urban technology constituted a large part of the programme and there was even the occasional session devoted to scientific research.

One notable feature of the meeting was that few of the sessions were devoted to discussion of scientific results, undiluted—or unenriched as the case may be—by considerations of public policy. That aspect reflects the desire on the part of the organisers to make the annual AAAS meeting more concerned with the interactions of science and society. It also reflects the fact that few scientists think of saving up their research results to announce them at the AAAS meeting—more specialised gatherings and quick-publication journals now fulfil that role.

● With Vice-President Rockefeller engaged in a study of how science advice should be plugged into presidential decisions, a session devoted to the question "Does the President still need a science adviser?" may seem like the height of irrelevance. But it turned out to be highly pertinent. Although only one member of a panel, consisting chiefly of luminaries from the world of science policy, ventured the opinion that the President has no need for a science policy office at his elbow, there turned out to be a huge spread of opinion on what the mechanism should be, and on what it should do.

Before the meeting took place, a few of the participants held a press conference at which two former officials in the Nixon White House confirmed what most people had suspected—that Nixon abolished the post of science adviser because he disagreed with much of the advice he was getting. Dr Edward David, Nixon's last science adviser, spoke of a "falling out"

between the President and the scientific community and said that "there definitely was a perception in the White House that the science advisers were using their expertise to grind axes". And Clay Whitehead, former Director of the White House Office of Telecommunications Policy, said that White House officials felt that the science adviser showed more allegiance to the scientific community than to the Administration.

New York diary

from Colin Norman

Most members of the panel thought that an office to provide policy analysis and advice on issues involving science and technology should be relocated near the centre of power. Franklin Long, of Cornell University, a former member of the President's Science Advisory Committee (which Nixon also abolished), favoured a three-member council of science and technology advisers. David also argued for a science policy office, but warned that it should be established in such a way that it does not upset the existing (and little noted) arrangements for getting science advice into the National Security Council and the Domestic Council. But George Reedy, former press secretary to President Johnson, argued that a full-time science adviser is not needed and that an *ad hoc* arrangement to provide scientific analysis of specific issues for the White House would be a better arrangement.

● A little light entertainment was provided later in the week by a debate—if a piece of comic opera can be so termed—over whether or not plants have been shown to respond emotionally to external stimuli. The debate took place between a number of botanists and Mr Cleve Backster, a polygraph expert and former CIA employee, who carried out an experiment in 1966 which, he claims, shows that plants respond electrically to human thoughts and emotions. That experiment has since turned up as the foundation of a best-selling book, the *Secret Life of Plants*, and resulted in widespread popular belief in the United States that plants have emotions.

Backster, an ebullient man who displayed a strong tendency to lead with his chin, failed to convince many of his critics that his experiment demonstrated anything other than poor scientific method, while two scientists who had tried unsuccessfully to repeat Backster's amazing work, failed to shake the belief of about half of the

audience in the emotional capacity of plants.

The crucial experiment, published in the Winter 1968 issue of the *International Journal of Parapsychology*, was carried out in Backster's New York laboratory. It was an attempt, in short, to see whether plants respond electrically to the termination of animal life.

He hooked three plants up to polygraphs, by sandwiching one of their leaves between electrodes, and monitored their electrical activity when brine shrimp were killed in a separate room. The shrimp were killed (terminated, Backster says in his paper), by being dumped into a bath of simmering water. Amazingly enough, the polygraph chart registered electrical responses similar to those which show up when human emotional reactions are monitored, and the results were statistically highly significant.

But two other scientists related their fruitless attempts to repeat Backster's work. Edgar L. Gasteiger, of Cornell University, told how experiments conducted over two years by three of his students "with many types of control that Cleve Backster did not use" failed to show any plant response to the killing of brine shrimp. The other would-be repeater of Backster's results was John Kmetz of the Science Unlimited Research Foundation—a body which Backster himself helped to establish. Kmetz used a total of 42 plants, 84 shrimp drops and 84 control drops using sterile water. His plants failed to react.

Although he has not repeated his original experiment, Backster, undeterred, claims to have achieved even more spectacular results with the bacteria in yoghurt. He claimed that when he added milk to one yoghurt culture, another culture across the laboratory which was hooked up to a polygraph gave off electrical signals. That piece of information, not surprisingly, got widespread attention from the press, for, as one journalist put it, "whose editor can resist a story about yoghurt that talks?"

Perhaps the chief question raised by the session was why was it held. Dr Arthur Galston, of Yale University, who arranged it, said that a poll of his students turned up the finding that about half of them talk to their plants, and about half of that group believes that it does some good. "There is a gap", he said, "between what scientists believe and what the lay public believes", and it is important to give the issue an airing. It must be the first time that an entire session of the AAAS has been devoted to a single experiment which has not been repeated in eight years, even by its originator.

news and views

RECENTLY our knowledge of the recipes which galaxies might use for cooking up heavy elements has increased rapidly. In an article in the *Astrophysical Journal* (193, 327; 1974) Peimbert and Torres-Peimbert report the detection of a difference of helium abundance between the interstellar gas in our own Galaxy, as observed in the Orion and η Carina nebulae, and ionised gas regions in the Large Magellanic Cloud, one of the nearest neighbours to our Galaxy. The difference is small (about 20%), but this is the first time a difference has been detected which is significantly greater than the observational and interpretive errors. Although the bulk of helium in the Universe is thought to have been synthesised in the big bang, further enrichment with helium comes through the nuclear conversion of hydrogen as the primary energy source for stars. The low helium abundance observed in the Large Magellanic Cloud implies that the gas in that galaxy has not been enriched as much as that in our own Galaxy. The present conditions in the Universe suggest that the big bang would have produced isotopes of hydrogen and helium, but no metals. The metals (which to an astronomer are anything heavier than helium) come from thermonuclear reactions during supernova explosions of stars which die with a bang rather than a whimper, the metals observed in the interstellar medium probably originating from stars with mass of more than ten solar masses. The low helium abundance of the Large Magellanic Cloud fits in very well with the observed low metal abundance for the same system—again this shows less enrichment by material processed in stars.

The determining factor in the amount of enrichment that takes place almost certainly involves the ratio of mass in stars to the mass in gas which is set up during the early fragmentation (or perhaps agglomeration?), collapse and evolution of a protogalaxy into a galaxy from the debris of the big bang. The rather irregular Magellanic Clouds have considerably more gas than our spiral Galaxy, in accord with the general observation of a rough inverse correlation between the metal abundance and gas content of galaxies. Just when and how many stars form (perhaps determined by the amount of angular momentum present), together with how much gas is left, will not only affect chemical evolution but may

Galactic cookery

from M. G. Edmunds

also determine the morphological type of the galaxy on the Hubble sequence—the reason why chemical evolution is of interest to all studies of evolution and dynamics of galaxies.

A first approach to models of chemical evolution, examined in some detail by Tinsley (*Astrophys. J.*, 192, 629; 1974), comes through observation of stars in our own Galaxy. It has been known for many years that the simple idea of stars forming, evolving and exploding at a uniform rate is inadequate. The metal abundances of stars can be deduced from spectroscopic analysis and their ages deduced by comparing their spectroscopic and photometric properties with theoretical stellar evolution models. The resulting relation of metal abundance with age shows puzzling features. Enrichment in metals has certainly not been uniform, but seems to rise rapidly during the early part of the Galactic life and to have increased only very slowly since then. Even some of the oldest stars seem to be metal rich. A second problem occurs because it is observed that the number of metal-poor dwarf stars is far too small compared with the number of metal-rich dwarfs to be explained by uniform enrichment. So what really happened? A popular proposal is that early on (perhaps even before the Galaxy had formed) the relative number of high mass stars to low mass stars formed was greater than for recent star formation. This shift in mass function, caused either by forming more massive stars or fewer less massive stars, implies more supernova metal synthesis per mass of gas converted into stars, and a rapid build-up of elements with only a few dwarfs formed before the Galactic gas became quite rich in metals. A change in the initial mass function for star formation is not as arbitrary as it might seem because the initially low metal abundance could radically alter both the cooling of the gas required for protostellar collapse and the mechanisms which limit the greatest mass which can condense into a star. The biggest uncertainty in all

models of galactic evolution arises because we just do not have a reliable theory of star formation—we have no way of predicting even whether a low metal abundance would shift the mass function towards higher or lower masses.

Playing around with the star formation in a rather different way has produced the attractive “metal-enhanced star formation” model of Talbot and Arnett (the latest in a series of papers appeared in *Astrophys. J.*, 190, 605; 1974). They propose that star formation at a given time only occurs in regions of gas which are more metal-rich than average, although there is some uncertainty whether or not large enough inhomogeneities in the metal abundance of the interstellar medium can be set up. Metals are preferentially incorporated into stars, the model accounts for the observed abundance versus time variations and the metal-poor dwarf problem, and has the additional attraction that a constant initial mass function is perfectly adequate. If this model is correct, it is telling us interesting things about star formation—the requirement for high metals and an invariable mass function.

In external galaxies, and probably our own, another phenomenon requires explanation. The abundance of metals is greater near the centre of a galaxy than farther out. How were such abundance gradients set up? Larson (*Mon. Not. R. astr. Soc.*, 166, 585; 1974) and Larson and Tinsley (*Astrophys. J.* 192, 293; 1974) have investigated numerically the collapse of a spherical protogalactic gas cloud with various boundary conditions, and simple assumptions about the conditions for star formation. Some of these models reproduce well the time variation of metal abundance, and also set up abundance gradients by the fall of gas, enriched by supernova explosions, towards the centre of the galaxy. Another feature is the prediction of an early peak in star formation and explosion which Larson suggests might trigger the onset of Seyfert or QSO behaviour in some massive galaxies. This has attractions as it suggests a quiescent ‘normal’ evolution of a QSO until it becomes superluminous, and would allow the build-up during the normal evolution of the observed (albeit rather uncertain!) approximately solar abundance of metals in quasar spectra. In his most recent paper (*Mon. Not. R.*

astr. Soc., **169**, 229; 1974) Larson adds a new refinement to his models in the effect of the energy input of the supernovae on the galactic gas. This energy tends to blow out of the galaxy the metal enriched gas as it falls towards the centre, the amount expelled depending on the escape velocity and hence the mass of the galaxy. This offers an explanation of the apparent correlation of the metal abundance of a galaxy with its absolute magnitude, from several times less than solar abundance for dwarf ellipticals with low escape velocities to a few times more than solar for massive ellipticals.

A rather imposing blend of an initial formation model and a collapse-infall model is being proposed by Ostriker and Thuan. From other arguments on galactic rotation curves and stability of galactic disks, Ostriker and co-workers have proposed that spiral galaxies have massive stellar holes containing perhaps up to ten times the mass of the disk. During initial collapse star formation is rapid, and the en-

riched gas expelled from massive stars falls to form the disk. The longer lived dwarf stars persist in the halo, sufficiently faint to escape visual detection, but still contribute a significant infall of material into the disk by mass loss from their surfaces. For all models the realistic inclusion of such effects as violent events in the nuclei of galaxies, sporadic star formation and radial gas flows is yet to come. But already we have the problem of non-uniqueness of models which will only be resolved by tighter theoretical and observational constraints. For example the useful limits on the amount of gas cycled through star formation from deuterium abundances (which is destroyed by passage through stars) can be used once it is clear whether or not the big bang was the only source of deuterium.

It seems that present galactic chemical evolution models are similar to culinary ones—they may vary greatly in their ingredients, but with judicious stirring a palatable cake may result from many of them.

The enigmatic protein

from Aubrey Knowles

It is nearly 100 years since Kuhne extracted a pink, light-sensitive material from the retinas of a number of animals. He realised that these substances—later called rhodopsins—were proteins and that they were responsible for the conversion of light into neural signals. Since then, a great deal of effort has been made to understand the rhodopsin molecule, but its structure is as mysterious as ever. This unique molecule is thermally quite stable, yet will undergo major chemical and structural changes on the absorption of a single quantum of visible light: beyond acting as a transducer of light, it is also the principal structural protein of the photoreceptor cell membranes.

This last factor has hampered investigation by the usual techniques of protein chemistry, for rhodopsin is a hydrophobic molecule and is totally insoluble—thus it cannot be crystallised. Until recently, most investigations have been carried out on detergent extracts, and the results of these are of questionable validity for all detergents denature the molecule to some extent. The detergent-extracted molecule has been found to contain, beyond the protein part, phospholipid, carbohydrate and a polyene called retinal. The latter is the 'chromophoric group' that gives the molecule its colour: exposure to light causes the chromophoric group to break away from its binding site, and the colour is lost. The supposition that the binding site is on

the protein part of the molecule has recently been confirmed, for nearly all of the phospholipid can be removed enzymatically without loss of colour (Borggreven, Daemen and Bonting, *Archs Biochem. Biophys.*, **151**, 1; 1972). It has also been found that up to 40% of the protein can be removed by proteolysis without causing bleaching (Bonting, de Grip, Rotmans and Daemen, *Expl Eye Res.*, **18**, 77; 1974; Trayhurn, Mandel and Virmaux, *FEBS Lett.*, **38**, 351; 1974; Saari, *J. Cell Biol.*, **63**, 480; 1974).

In 1968, Heller (*Biochemistry*, **7**, 2906 and 2914) showed that rhodopsin protein can be separated by gel filtration chromatography, and that it behaves as a globular protein of molecular weight about 28,000 and diameter 46 Å. The retinal molecule has a molecular weight of only one-hundredth of that of the protein, but since it is about 15 Å long, if it is visualised as fitting into a binding site on the surface of the protein, it will span a considerable arc of the circumference. In fact, Saari claims to have removed many of the hydrophilic groups of the protein, which apparently lie on the surface, without disturbing the chromophoric group, and so the binding site may well be a cleft in the interior of the protein. In either case, the chromophoric group will lie in close proximity to a large number of the amino acid residues of the protein—close enough for electrostatic or dispersive forces to act between them.

Absorption maxima

It is this interaction that gives the rhodopsin molecule its unique spectroscopic properties. All known creatures with image-forming visual systems employ a rhodopsin-type visual pigment, and the absorption maxima of these pigments lie over a colossal range of wavelengths throughout the visible and near-ultraviolet regions. The gamut of rhodopsins has been extended down to 345 nm by the confirmation by Paulsen and Schwemer (*Biochim. biophys. Acta*, **283**, 520; 1972) that the pigment of the neuropteran, *Ascalaphus macaronius*, is a true rhodopsin. The retinal-based pigment of longest wavelength is that of the bronze turkey (*Meleagris* sp.), with a maximum at 562 nm. Thus any theory of pigment absorption must explain how the absorption maximum of retinal at about 380 nm can be either blue-shifted by 35 nm or red-shifted by up to 182 nm. Various theoretical models have been put forward in the past, but the most popular at present is based on a single covalent bond—a protonated aldimine (Schiff's base) linkage—between retinal and an ε-lysine group on the protein. This will cause the retinal absorption maximum to be red-shifted by up to 100 nm, and the fine tuning required to give the absorption maxima of different species is then achieved by secondary interactions between the chromophoric group and other amino acids. This can be pictured in its simplest form as the effect of a single negative charge fixed at a certain point near the polyene chain. Recent detailed molecular orbital calculations show that as this counter-charge is moved away from the positive charge at the aldimine bond, the absorption maximum goes to longer wavelengths, approaching a limiting value similar to that found in nature (Waleh and Ingraham, *Archs Biochem. Biophys.*, **156**, 261; 1973; Suzuki, Komatsu and Kitajima, *J. Phys. Soc. Japan*, **37**, 177; 1974).

Retinal can form a number of geometrical isomers, but only one of these, the 11-*cis*-isomer, will react with bleached rhodopsin to regenerate the original pigment. For this reason, it has been assumed that the conformation of the chromophoric group in the binding site is 11-*cis*, and that the shape of the molecule is the same as is found in crystalline 11-*cis*-retinal. Gillardi, Karle and Karle (*Acta Cryst.*, **28B**, 2605; 1972) showed that crystalline 11-*cis*-retinal is not planar like the other isomers, but is twisted and should thus be optically active. The intact rhodopsin molecule shows a circular dichroism associated with the long wavelength absorption band that is not seen in solutions of 11-*cis*-retinal. Honig, Kahn and Ebrey (*Biochemistry*, **12**, 1637;

WHETHER the study of the orientation of ancient monuments ranks as a science or a pseudo-science remains a matter for debate, but there can be no doubt that the topic is once again attracting a great deal of attention. Having formed a focus of interest in the latter years of the nineteenth century and early in the twentieth century, studies of orientation went into decline in the inter-war years partly, perhaps, because of factors such as excessive emphasis on allegedly significant orientations in Nazi Germany, and partly because the different groups of people involved—mainly astronomers and archaeologists—had failed to agree on the reality and significance of the results.

The recent revival of interest in orientation studies has arisen mainly from new detailed surveys of megalithic sites in the UK, especially those carried out by professor Thom since his retirement from Oxford. He has used these measurements in two ways—to identify the astronomical events indicated by the orientations and to consider the actual layout and scale of the monuments. The consensus of opinion at a recent joint meeting of the Royal Society and the British Academy on ancient astronomy tended to be that the deductions concerning astronomical orientation had firmer bases than those relating to the existence of a standard measure of length in megalithic times. Certainly the former have excited the more discussion. For, unlike most archaeological discoveries which illuminate primarily material culture, they could give a direct, if partial, insight into the level of intellectual sophistication that had then been reached.

Astronomers have in general contributed to the recent growth of interest in studies of alignments more by theoretical speculation than by on-site surveying. Indeed, much of the controversy engendered by the claimed alignments has hinged on the alleged extravagances of some of these

Ancient observatories

from A J Meadows

speculations (especially regarding the astronomical implications of Stonehenge). The crucial point behind both the speculations and the arguments hinges on the significance of any measured orientation. After all, astronomical objects have to rise and set somewhere on the horizon—could not the observed alignments be purely coincidental? How convincing an answer can be given to this question depends critically on the accuracy and uniqueness of the data collected.

A group from the Cambridge University Astronomical Society has now re-surveyed with increased accuracy three sites previously described by Thom (this issue of *Nature*, page 431). The most interesting of the three sites is that at Ballochroy in Argyllshire (which Thom has described as one of the most important he knows for observing the solstitial Sun). The new measurements not only support Thom's claim, they also produce a set of dates for the various orientations present that agree remarkably well among themselves, and convincingly suggest that the stones were erected for use around the date 1600 BC. But the other two sites surveyed—at Loch Seil and Loch Nell, both also in Argyllshire—provide much less satisfactory evidence. At Loch Seil, the suggested alignments seem to be non-existent, and at Loch Nell, although the alignments are clearly defined, they do not point to any obviously significant astronomical event.

The sceptic might reasonably comment that one interpretable site out of three suggests that chance may well play a part in producing apparently significant orientations. But chance

would be unlikely to produce orientations that agree with respect to dating, as do those found at Ballochroy. Besides, disturbances must certainly have occurred at some sites during the past four millennia, disrupting alignments that were originally there, and making interpretations ambiguous. The interesting discrepancies are rather those, as at Loch Nell, where the intended alignment seems obvious, but the astronomical explanation does not, for this raises the question whether all, or even the majority of, megalithic monuments were really intended to serve as astronomical observatories. One comment is worth making on this: there is still a need to consider all astronomical bodies that might have attracted attention in megalithic times. So far, attention has concentrated mainly on the Sun, Moon and a few bright stars. However, the planets, especially Venus, were surely equally important in ancient astronomy. The problem, in terms of orientation studies, lies in distinguishing between solar and planetary positions on the horizon.

If we compare studies carried out in recent years with those occurring earlier in the century, the only apparent difference in practical terms is an increase in the accuracy and extent of the site surveys. Why then has the subject re-erupted into the news? I would guess that one reason is a new pervasive interest in the influence of astronomical (or astrological) ideas on the thinking of early man. This is reflected in recent discussions of the astronomical implications of myth, noticeably the detailed analysis in *Hamlet's Mill* by G. de Santillana and H. von Dechend. It appears, too, in the debate over very early archaeological material that, according to A. Marshack, indicates a primitive lunar notation. All these topics are controversial, but, in combination, they suggest the intriguing conclusion that man was numerate long before he was literate.

1973) have suggested that this is due to the stereospecificity of the binding site, which can select one enantiomer from a solution of 11-*cis*-retinal, and thus confer optical activity on the visible absorption. On the other hand, Johnston and Zand (*Biochemistry*, **12**, 4637, 1973) have shown that model aldimines of all-*trans*-retinal with some optically active amines show circular dichroism, so long as the amine has an aromatic group that can couple with the long-wavelength absorption band of the retinal. Thus the fact that rhodopsin shows circular dichroism in

the visible region implies only that the chromophoric group is bound to an optically active amino acid, and that there are aromatic amino acids near the binding site. The retinal is not necessarily in a dissymmetric conformation.

Intact retina

Another physical method of great potential in probing the structures of coloured molecules in biological milieux is the resonance-enhanced Raman effect. In 1970, Rimai, Kilponen and Gill (*Biochem biophys Res Commun*, **41**, 492, 1970) showed that using this

technique it is possible to study the chromophoric groups of rhodopsin molecules in the intact retina, and thus provided the first direct evidence that the retinal is bound in the form of an aldimine. The intense 488 nm exciting light used in these experiments bleached the rhodopsin, but it has since been shown that use of a 583 nm dye laser permits the recording of the Raman spectrum without undue bleaching, and so it could be established that the chromophoric group is probably in the 11-*cis* conformation (Lewis, Fager and Abrahamson, *J Raman Spect*, **1**, 465,

1973) Unexpected bands in the 550–950 cm^{-1} region are ascribed to interactions of aromatic amino acids with the chromophoric group—perhaps these are the same interactions that determine the absorption maximum of the pigment. Confirmation that the aldimine linkage of rhodopsin *in situ* in photoreceptor membranes is protonated has recently been presented by Oseroff and Callender (*Biochemistry*, **13**, 4243, 1974), who also studied the effect of light on the pigment at low temperatures. Illumination gives an equilibrium mixture of rhodopsin and two products, isorhodopsin and bathorhodopsin, which are all interconvertible by light. The conversion of rhodopsin to isorhodopsin requires isomerisation of the chromophoric group from the 11-*cis* to the 9-*cis* form, and the conversion to bathorhodopsin was previously thought to involve isomerisation to the all-*trans* form. However, Oseroff and Callender conclude that the retinal in bathorhodopsin is not in any conformation known from studies of solutions. Bathorhodopsin is the first of a series of intermediates seen in the bleaching of rhodopsin at normal temperatures; the absorption maxima of these lie between 543 and 380 nm, and it is tempting to think that these represent stages in the twisting of the chromophoric group as it progressively breaks free of the binding site. Resonance Raman spectroscopy promises to be a splendid tool in the study of these intermediates, and may also explain the mechanism that determines the absorption maxima of the rhodopsins from different species.

Another component of the rhodopsin molecule that is in the news is the carbohydrate moiety, originally identified by Heller and Lawrence (*Biochemistry*, **9**, 864, 1970) who suggested that it acts as a marker on the surface of the molecule to ensure its correct orientation on assembly into the photoreceptor membrane. Renthal, Steinemann and Stryer (*Exp Eye Res*, **17**, 511, 1973) have since established that it is not involved in the binding site, for chemical modification of the carbohydrate does not prevent the regeneration of bleached pigment. The group also provides a convenient point of attachment for a 'fluorescent probe' molecule, and a study of energy transfer between the probe and the chromophoric group suggests that these are separated by between 51 and 65 Å—more than the apparent diameter of the protein. This may mean that the rhodopsin molecule is ellipsoidal, or could be explained by the recent studies of Romhányi and Molnar (*Nature*, **249**, 486, 1974) who have shown by light-microscope histological methods that the saccharide chains of the rhodopsin molecules in fixed frog receptors point

outwards from the molecule. It is suggested that these extend into a hydrophilic region in the receptor membrane, and serve not only to anchor the molecule in a fixed orientation but also to act as a pivot for its rotation. Surprisingly, Saari reports that proteolysis does not remove the carbohydrate moiety, even though this degradation is thought to involve the hydrophilic parts of the molecule most remote from the chromophoric group.

We are in an exciting era of visual pigment research, when many of the old dogmas are being re-examined and new physical techniques now permit measurements to be made on the behaviour of rhodopsin in intact photoreceptor cells. Perhaps we shall soon have a real insight into the structure—and finally the function—of this strange molecule.

Basin tectonics

from A Hallam

It is no discredit to the elegant simplicity of plate tectonics that only in the oceanic sector does it throw significant new light on vertical (as opposed to lateral) motions of the Earth's surface. Plate tectonics revolutionised the study of structural evolution by accounting for major tectonic features of the Earth by comparatively few lateral motions and interactions of lithospheric plates. Not surprisingly, the success of the new concept pushed into the background related problems which have been wrestled with since the time of Lyell and Darwin—problems associated with the uplift of continental mountain ranges and plateaux and the subsidence of basins or continental margins. In the preparation of dishes for the connoisseurs of world tectonics we seem to have become obsessed with plates and neglected basins.

The widespread indications of marginal downwarping of continents such as seaward descent of erosion surfaces and warping of marine terraces, seaward dip and thickening of Cretaceous and Tertiary sediments, palaeogeographical evidence of founded offshore land areas and, more controversially, submarine canyons, led many geologists to agree with Kuenen's judgement of a quarter century ago that it was "difficult to avoid the conclusion that marginal areas have subsided to form part of the present deep sea floor". Now isostatic considerations demand that this could only happen if the continental crust were substantially thinned or in some mysterious way converted into denser oceanic-type crust. The Soviet tectonician Belousov has gone so far as to invoke extensive 'oceanisation' of continental crust to

account for the ocean basins, he has in consequence totally rejected plate tectonics and explains first order structures exclusively by vertical motions. One need not go so far as to adopt this extreme heretical position to accept that something strange and as yet inadequately explained has been going on at continental margins.

Subsidence of parts of the North Atlantic continental margins has recently been shown by geophysical work and deep sea drilling to be even more extensive than recognised hitherto. Thus Talwani and Eldholm (*Bull Geol Soc Am*, **83**, 3575, 1972) have demonstrated that the Voring Plateau off Norway, occupying an average depth of 2,000 m, is subsided continental rather than oceanic crust, with an eastward-descending ridge of probably Precambrian basement buried beneath a considerable thickness of Palaeozoic and younger sediments, it can thus be compared with, for instance, the Rockall Bank. East of Newfoundland is another area of deep sea floor which gives indications of being subsided continent (Ruffman and van Hinte, *Geol Surv Can Paper* 71–23, 407, 1973). Drilling on the Orphan Knoll seamount has located Middle Jurassic continental coal measure deposits, which points indubitably to over 2,000 m of subsidence since that time. Ruffman and van Hinte argue for a much more extensive subsidence, of as much as 3,500 m, of a vast area of deep sea floor to the south and west of Orphan Knoll.

This work has some interesting implications. It suggests for instance that the so-called Quiet Magnetic Zone is not, as most geophysicists have assumed, true oceanic crust produced by spreading at a time of no magnetic reversals, but subsided continental margin, as I inferred a few years ago (*J Geol*, **79**, 129, 1971). This would explain why the position of the Quiet Magnetic Zone is always near the continental margin irrespective of the postulated age of oceanic opening. Second, the common acceptance of the 1,000 m isobath as the effective edge of the continents for the purpose of least squares fits, to obtain their pre-drift positions, is seen to be inaccurate and leads to their being placed too close together. This could well account for the most awkward feature of the celebrated Bullard fit of the Atlantic continents, namely the lack of space for Central America. In terms of plate theory the marginal downwarping can be explained as follows. Prior to or contemporary with initial oceanic rifting the continental crust was bowed up by expanding hot mantle and thinned slightly by erosion but more substantially by tensional stretching accommodated by normal faulting. As the continents subsequently moved apart

Hexokinase in human muscular dystrophy

from a Correspondent

CONTROVERSY abounds at the moment about the pathogenesis of the severe X-linked form of muscular dystrophy, which is known as the Duchenne type and which usually results in the affected boys being unable to walk by the age of about 10 years and rarely surviving beyond the age of 20. Within recent years McComas, Sica and Currie (*Nature*, **226**, 1263, 1970) have suggested that the progressive degeneration of skeletal muscle which occurs in this condition may be the result of a primary defect in the motor neurones, whereas Hathaway, Engel and Zellweger (*Archs Neurol*, *Chicago*, **22**, 365, 1970) have postulated a process of progressive ischaemia of muscle because of a superficial similarity of the pathological changes in skeletal muscle in such cases to those produced by experimental muscle embolism in animals. These hypotheses have challenged the traditional view that this and other forms of genetically determined muscular dystrophy are likely to be due to a primary biochemical abnormality of the muscle cell itself, though it is certainly possible that a genetically determined biochemical defect could influence the function of both motor neurones and skeletal muscle.

Ellis, Strickland and Eccleston (*Clin Sci*, **44**, 321, 1973) have previously found that muscle obtained by biopsy from patients with Duchenne type muscular dystrophy is less able than is normal muscle to utilise glucose by the usual pathway of glycolysis. They found that in such tissue there was partial conversion of glucose to fructose instead of to glucose 6-phosphate under certain metabolic conditions. The

conversion of glucose to glucose 6-phosphate is normally catalysed by hexokinase, an enzyme present in mammalian tissue in the form of several isoenzymes which differ in their K_m values for glucose.

Strickland and Ellis have now found certain abnormalities of hexokinase isoenzyme mobility when studied electrophoretically in muscle obtained from patients suffering from X-linked Duchenne type muscular dystrophy and the similar but more benign X-linked Becker variety (this issue of *Nature*, page 464). They find that tissue obtained from patients with these two diseases shows three, instead of the normal two, bands for hexokinase, two of which move relatively faster than do the bands of the normal isoenzyme II, and an additional slower-moving band close to isoenzyme I. Similar isoenzyme changes were found in liver, brain and sciatic nerve obtained at post-mortem from patients with Duchenne type muscular dystrophy. As the authors point out, this alteration in hexokinase isoenzyme II in a number of tissues obtained from patients with muscular dystrophy might account for a restricted flow of glucose through the hexokinase step in tissues where isoenzyme II is required. If such an abnormality were to prove to be of fundamental importance in the pathogenesis of muscular dystrophy, it could certainly account for abnormalities in the function of both neurones and muscle cells in this disease. Confirmation of this work and further studies of hexokinase isoenzyme behaviour in muscle and other tissues obtained from patients with X-linked muscular dystrophy will be awaited with interest.

the trailing margins continued to subside as the newly created ocean floor cooled progressively and hence became more dense. It remains to be seen whether this model can account in a satisfactory quantitative way for several thousand metres of subsidence since the early Cretaceous, apparently regardless of the age of opening.

Although the Atlantic margins offer interesting problems their solution seems relatively straightforward compared with those posed by substantially land-locked marine basins such as the Gulf of Mexico, the Black Sea and parts of the Mediterranean Sea. For the Black Sea Brinkmann (*Am Ass Petrol Geol Mem*, **20**, 63, 1974) has

outlined the abundant palaeogeographical evidence that it was the site of a terrestrial sediment source for much of the Palaeozoic and early Mesozoic. Yet seismic surveys reveal that the crust underlying the Black Sea has suboceanic thicknesses. Probably the most plausible interpretation of the existing data is that thick Upper Cretaceous and Tertiary sediments rest on a much attenuated continental crust. The obvious question arises, what has caused the thinning? Unlike the case of the Atlantic margins it cannot readily be related to a generally accepted plate tectonic model.

The case of the Mediterranean basins is perhaps even more intriguing, since

we have two quite different interpretations of their origin, one invoking lateral, the other vertical movements. Western Mediterranean basins such as the Balearic Basin and Tyrrhenian Sea have a crust which is at least suboceanic if not fully oceanic in character, though no magnetic anomalies indicative of seafloor spreading have been discovered. Palaeomagnetic evidence for the anticlockwise rotation of Corsica, Sardinia and Italy has been held to confirm Carey's proposal that the western Mediterranean basins are sphenochasms, that is, wedge-shaped sectors of ocean floor created by the movement apart of slabs of continent. Hsu and others have adopted this model to account for the existence in the deep basins of substantial deposits of late Miocene NaCl and CaSO₄ salts which bear the characteristics of continental salina and sabhka deposits. To explain this apparent paradox a boldly imaginative hypothesis has been put forward (Hsu, *Nature*, **233**, 44, 1971; Hsu *et al*, *Init, Rep Deep Sea Drilling Project*, vol 13, 1203, 1972). After Africa closed on Europe during the early Tertiary and sphenochasms opened up in the intermediate zone, a stage was reached when a series of land-locked basins several thousand metres deep were created in the Miocene. Because the climate was warm and arid the Mediterranean remained substantially dry, except for shallow brine pools in the deep basins, where salts began to precipitate. River canyons were cut down as much as 2,000 m through the surrounding continental margins to a base level well below ocean level. Subsequently, in the Pliocene, the Straits of Gibraltar were opened up and sea water flooded in from the Atlantic, rapidly drowning the basins and canyons and allowing normal deep sea muds to be deposited. As a defence against an admittedly extravagant, though attractive, hypothesis, Hsu has quoted Sherlock Holmes: "When you have excluded the impossible, whatever remains, however improbable, must be the truth."

But can the 'impossible' be excluded?

Let us consider some other facts. There is an old idea that the Tyrrhenian Sea, like the Black Sea, is the site of a subsidised landmass. This idea has received impressive support from the dredging of continental metamorphic rocks from the margin of a tilted fault block in the centre of the sea, implying late Tertiary subsidence in excess of 3,000 m (Heezen *et al*, *Nature*, **229**, 327, 1971). The occurrence of a parallel series of ridges and troughs suggests a series of fault blocks like the Great Basin regime of the western United States and implies considerable thinning of continental crust by tension. More recently, combined geophysical

and stratigraphical work in the Balearic Basin and the margins of Catalonia has provided strong support for substantial subsidence in the recent geological past (Stanley *et al*, *Geology*, 345, July 1974). Prominent stratigraphical horizons of Miocene or younger age have been demonstrated to be downwarped or down-faulted towards the basin floor by as much as 2,000 m. The submarine canyons evidently result from the drowning of previously emergent land margins to depths of more than 1,000 m. In other words the Miocene salt was originally deposited at or slightly above sea level and has subsequently subsided with the underlying crust.

One of these explanations must be wrong. If we are to adhere to Hsu's hypothesis how are we to account for the apparently good evidence of basinal subsidence? If accordingly we reject it we must presumably also reject the palaeomagnetic evidence for the rotation of Corsica, Sardinia and Italy and must also try to explain up to 3,000 m subsidence in the last 15 million years, and the substantial loss of continental crust. Is there any correlation between the basin subsidence and the uplift of certain circum-Mediterranean mountain areas? To give just one instance, locally in Tunisia there has been at least 3,000 m uplift since the late Miocene. If the crust has been thinned by tension this must presumably have operated radially, as also would be the case in the Gulf of Mexico, which similarly has oceanic crustal structure, buried salt (probably Jurassic) in its deepest part and suggestions from palaeogeography of occupying the site of an ancient landmass. To what extent are the pronounced changes in elevation a consequence of changes in crustal thickness or density, or variations in density of the upper mantle? Can the underlying phenomena be readily reconciled with our present geophysical concepts, which lean heavily on plate tectonics, or are other mysterious forces at work?

My dear Watson, it's not so elementary!

Oceanic ridges as collapse calderas

from Peter J. Smith

THERE are obvious differences, both in structure and behaviour, between the long linear oceanic ridge and the geographically localised volcano. But there are also significant similarities, for in their active forms both features are associated with very young volcanic rocks, rocks which have undergone high temperature metamorphism and high heat flow. Moreover, some volcanoes produce lavas similar to the basalts found on the ocean floor. These

A hundred years ago

THE words of Mr Disraeli on Monday night with regard to University Reform are also very cheering to those who wish to see some decided action taken towards the thorough reform of our Universities. Mr Disraeli's words were very strong, so strong indeed as to amount to an assurance that Government really means to take into serious consideration this session the Report of the University Commission. "It is our opinion," the Prime Minister said, "that no Government can exist which for a moment maintains that the consideration of University Reform, and consequently legislation of some kind, will not form part of its duty." These words give out no uncertain sound. Mr Disraeli said, moreover, that when the Report was presented at the end of last session, the Colleges were not assembled. It would be interesting to know whether the Colleges have yet met to consider the Report, and whether they are likely to act on this hint of the Premier and take some internal action—commence the work of reform from within, instead of waiting until they are driven to it by forces from without.

from *Nature*, 11, 292, February 11, 1875

characteristics suggest that ridge axes may be underlain by magma chambers at a depth of a few kilometres. Is it possible, then, that the study of volcanoes with magma chambers will help in the understanding of the less accessible ridges?

In the hope that such a comparison would be illuminating, Francis (*Geophys J*, 39, 301, 1974) has analysed the activity of the Fernandina Caldera (Galapagos Islands), whose floor collapsed in 1968. In the early part of that year, Isla Fernandina, a large basaltic shield volcano, had an elliptical caldera with a flat floor about 7 km² in area. But on June 11 the caldera floor began to subside in a series of short bursts and along a steep pre-existing elliptical boundary fault. According to Simkin and Howard (*Science*, 169, 429, 1970), the increase in caldera volume caused by the collapse was 1–2 km³, and the lowering of the floor (unevenly) by an average of 150 m represented a potential energy loss of 10²³–10²⁴ erg.

The seismic energy released was several orders of magnitude lower than this (10¹⁹–10²¹ erg), but its effect was hardly less spectacular. Whereas in 1967 and 1969 earthquakes were reported from the area at an average rate of about one every two months, at

least 599 shocks occurred during the period 12–23 June, 1968. The largest of these events, most of which were shallow, had maximum magnitudes $m_b=5.4$ and $M_s=5.2$. But more significantly, the magnitude–frequency plot, whether using m_b or M_s , is best fitted by two straight lines rather than one; there is a definite change in slope (b value) at about $m_b=4.9$ or $M_s=4.5$.

The two distinct b values for M_s data were first recognised by Filson *et al* (*J Geophys Res*, 78, 8591, 1973), who were, however, unable to explain them. But Francis has now been able to extend the Filson model to give a straightforward explanation of the seismic data. The caldera floor is regarded as the top of a plug capping a magma chamber (plug and chamber being cylindrical in the simplest form of the model). The fact that the Fernandina caldera collapsed along a pre-existing fault surface implies that under normal circumstances the plug is not supported structurally but by the pressure of the magma beneath. A collapse will occur when, for one reason or another, the magma chamber pressure is reduced to the point at which the shear stress on the fault surface exceeds the fault strength. When this happens, the plug will fall to a new equilibrium position.

From the model, and using a modified form of Press's (1967) formula relating fault length to earthquake magnitude, Francis shows that the maximum magnitude of shocks produced along the main caldera fault should be about 5.4 (m_b). This agrees with observation. But a model involving a falling rigid plug is not entirely satisfactory insofar as, in the real Fernandina collapse, further faulting occurred at the north-west end of the caldera. Here there was no appreciable subsidence, and flexing of the caldera floor produced a band of fractures aligned normal to the caldera's long axis. The length of this fracture zone is an order of magnitude smaller than that of the main fault and the predicted maximum magnitude of shocks from the zone is correspondingly low at $M_s \sim 4.0$.

Further calculation shows that the larger shocks produced at the main fault are associated with low average stresses and small stress drops—which implies high b values. By contrast, the tensional fracturing in the north-west has stresses comparable to the average stresses for most earthquakes, the b values are thus also comparable (normal). In other words, the two distinct b values observed for the Fernandina collapse swarm arise from two different types of earthquake.

So the seismic characteristics of the Fernandina caldera collapse are broadly explicable in terms of observed physical processes. But how does this relate to oceanic ridges? The point that

Francis makes is that in many respects the seismicity of slow-spreading ridges (fast spreading ridges such as the East Pacific rise are rather different) is similar to that of the caldera collapse episode. At the mid-Atlantic ridge, for example, all earthquakes are shallow and none is very large (maximum $m_b \sim 5.6$ in rift zone), rift zone earthquakes seem to be confined to the median valley, the b value of rift zone events is usually significantly higher than for transform fault events, rift zone events exhibit normal faulting, and earthquakes swarms are common along rift zones. Moreover, earthquake swarms associated with spreading axes in the Gulf of California have been shown to be low stress events.

Francis thus proposes that rift zone seismicity along slow-spreading ridges is generated by a series of caldera collapses. The median valley floor of the mid-Atlantic ridge, for example, is constantly collapsing at various points, the locations of which will be governed by the configuration of the magma chambers and of the overlying topography. Generally, collapse will occur along pre-existing faults, although when such faults have moved outside the influence of the magma chamber (by lithospheric spreading) new faults will form along the chamber's lateral limits. The width of the median valley floor thus roughly defines the maximum width of the magma chamber.

Where is the myosin?

from Dennis Bray

THE history of muscle research would have been very different if striated muscle had not been built in such a well ordered fashion. The almost crystalline myofibrils, composed of parallel filaments in segmented arrays, first caught the eye of light microscopists and later provided material for electron microscopy and X-ray diffraction. The information they provided on the positions and mode of interaction of the two kinds of elemental filament was unique and independent of biochemical analyses of their component proteins, such as actin or myosin.

Curiously, we are now in precisely the opposite position with non-muscle cells. Most eukaryotic cells have been shown to contain proteins that are chemically very similar to actin and myosin and which probably work in the same way, at the molecular level, as their counterparts in muscle. But, with the exception of the bundles of actin-like filaments that some cells possess close to their membrane surfaces, we have little idea where these proteins are within the cell. How they might be linked to other cellular constituents, or produce coordinated movements, are still open questions.

Some of the difficulties in placing these proteins within the cell are illustrated by the variety of results recently reported for myosin. The myosin of blood platelets and cultured fibroblasts seems to be more soluble than muscle myosin, and does not condense so readily into thick filaments at physiological ionic strength. If these cells are disrupted and subcellular fractions prepared by differential centrifugation (in the now time-honoured way) then most of the myosin is found in a soluble, non-sedimentable form (Ostlund, Pastan and Adelstein, *J. biol. Chem.*, **249**, 3903, 1974). To judge from this direct and quantitative method most of the myosin is freely diffusing within the cell, either as single molecules or as small aggregates.

Yet if a different technique is used a different answer is obtained. The recent work of Weber and Groschel-Stewart (*Proc. natn. Acad. Sci. U.S.A.*, **71**, 4561, 1974), in which cultured fibroblasts are fixed and exposed to anti-serum to uterine myosin, shows that at least part of this protein is to be found in filaments. The striking pictures they obtained by immunofluorescence show long straight strands extending across the cell, often in parallel alignment, and with a periodicity in the staining revealed at higher magnification. Since there is some reason to think that these strands may also contain actin an arrangement similar to that in myofibrils may be present, and it is tempting to think that such strands may be able to contract.

And the possibilities do not end there. Again using immunofluorescent techniques but this time applying them to intact cells, two laboratories have reported the presence of myosin on the outer surfaces of cells (Gwynn *et al.*, *J. Cell Sci.*, **15**, 279, 1974; Willingham *et al.*, *Proc. natn. Acad. Sci. U.S.A.*, **71**, 4144, 1974). Conscious, perhaps, of the unexpected nature of their findings these workers have carried out extensive controls. Willingham and co-workers in particular, compared antisera to three types of myosin: fibroblast, smooth muscle and striated muscle, and found that only the first of these gave the surface reaction. Among other tests, they carried out the important one of absorbing anti-serum to the cells and showing that upon elution it still cross reacted with myosin.

It is true that immunological evidence in the absence of direct biochemical tests is hard to defend against all objections. Myosin, in particular, is a difficult protein to purify and few would claim that their preparation could not contain up to 5% of other components, perhaps from the surface. In addition, the possibility of adventitious contamination by myosin from

lysed cells is always present. Nevertheless, an interaction of contractile proteins with cellular membranes is now widely expected and could have as a consequence the exposure of part of the myosin molecule to the outside of the cell. It will be most exciting if this is true, and worth the search for independent methods of testing.

The present picture seems confusing. We have evidence that myosin is free within the cytoplasm, present in strand-like filaments, and closely associated with the cellular membrane. But these are not necessarily incompatible results. Only one of the methods used to detect myosin is quantitative—that of measuring its ATPase activity—and the immunological results could apply to only a small fraction of the myosin within the cell. It is entirely conceivable that this protein could exist in more than one state of aggregation or be associated with more than one subcellular structure. If so, then the factors that control its distribution will necessarily be critical for the movements of the cell.

Proline implicated in halophyte osmotic adjustment

from Peter D. Moore

JUST as adaptations to cold and to heat seem to go hand in hand (*Nature*, **253**, 11, 1975), so do adaptations in many plants to drought and salinity. Water-stressed plants of several species (for example broad bean, Stewart *et al.*, *Plant Physiol.*, **41**, 1585, 1966, and barley, Singh *et al.*, *Nature new Biol.*, **236**, 188, 1972) have shown an accumulation of the free amino acid proline. Singh *et al.* showed that different varieties of barley had different capacities for the accumulation of proline in response to water stress.

Waldren and Teare (*Plant and Soil*, **40**, 689, 1974) have now examined proline levels in intact plants of sorghum and soybean and at the same time measured stomatal diffusive resistance and leaf water potential as indications of water stress. In soybean, proline only began to accumulate when the stomatal diffusive resistance exceeded 37 s cm^{-1} and when a leaf water potential of -14 bar was reached. By this time the plants showed loss of turgor. In the case of sorghum, proline accumulation occurred only when stomata were completely closed and when the leaf water potential had reached -24 bar. Again, incipient wilt was evident at this stage, so proline concentrations cannot be regarded as a sensitive indication of water stress for these species.

This type of association of free proline with drought response in plants

has led Stewart and Lee (*Planta*, **120**, 279, 1974) to investigate the possibility that proline may be associated with the tolerance of physiological drought in halophytes. They analysed the free amino acid content of a number of halophytes from salt marshes in western Britain and found that in many (for example *Aster tripolium*, *Armeria maritima*, *Puccinellia maritima* and *Triglochin maritima*) the concentration of proline was higher than that of any other single amino acid, often by a factor of ten. In some species proline represented 70% of the free amino acids and in most it exceeded 30%. But *Plantago maritima* had a low proline content, this exception demonstrates that proline accumulation is not a universal feature of halophytes.

Using *Triglochin maritima* Stewart and Lee were able to show that proline build-up is enhanced by high salinity in the surroundings, just as Waldren and Teare had demonstrated in the case of water stress. They also found that different populations of certain species, which were geographically isolated and which had experienced different salinities over long periods of time, had varying capacities for the accumulation of proline. For example, *Armeria maritima*, the thrift, is a species which occurs both as a maritime halophyte and as a species of arctic-alpine habitats on many British mountains. Palaeoecological studies suggest that the species was widespread in distribution during the cold and disturbed conditions at the close of the last glaciation, some 10,000 years ago. Populations have subsequently been isolated on mountain tops and coastal habitats as forest has spread and eliminated this shade-intolerant species from many habitats. When tested under a variety of salinities, *Armeria* populations from inland situations showed only a limited capacity for proline accumulation. The response of coastal *Armeria* samples was about three times as great as those from inland. Such a difference in response is reminiscent of the varietal adaptation to proline accumulation as a response to drought found in barley (Singh *et al.*, 1972).

It is known that the enzymes of some halophytes are not able to operate in media of high salt concentration (for example, the work of Flowers, *J exp Bot*, **23**, 310, 1972, on *Sueda maritima*). Sodium chloride within halophytes must, therefore, be physically separated from the cellular enzyme systems, presumably by storage in the vacuole. Stewart and Lee have examined the effect of elevated proline levels upon the activity of several enzymes in *Triglochin maritima*, they found no depression of activity. They suggest, therefore, that proline could provide the means of cytoplasmic osmotic

adjustment in those halophytes where proline accumulation has been observed. Perhaps it serves a similar function in drought-stressed tissues where osmotic compensation may be required within the cytoplasm of affected cells. Apart from the elucidation of the precise role of proline in these processes, one of the most interesting developments in this work is likely to emerge from the exceptions to the general rules—exceptions like *Plantago maritima*.

Laser studies of atomic and molecular collisions

from G Duxbury

In the last fifteen years there has been an increasing interest in the experimental and theoretical study of the energy transfer processes occurring in atomic and molecular collisions. One of the main experimental techniques which has been used is that of crossed molecular beams, which requires very expensive ultra-high vacuum apparatus. An alternative way of obtaining the information is based upon experiments using single frequency narrow linewidth lasers. In these experiments use is made of the velocity selective interaction of monochromatic radiation with gaseous atoms and molecules. The information obtained from the laser experiments is similar to that from the crossed beam experiments, but does not require ultra-high vacuum techniques for its success. In addition, information can be gained, not only on the changes of translational energy, but also on changes in rotational energy. As examples of the types of experiment that can be carried out, two different ones are described, one of which has been carried out and one which has recently been proposed.

If a single-frequency laser emits radiation of frequency ν which differs slightly from the resonance frequency ν_0 of the atoms or molecules which absorb the radiation, the Doppler shift will make the laser radiation appear exactly on resonance only for those molecules whose component of velocity along the laser beam is $v = c(\nu - \nu_0)/\nu_0$, where c is the velocity of light. If the molecule irradiated is allowed to collide with a heavy target, the velocity dependence of the collision cross section for the production of a particular excited state can be determined by measuring the ratio of the fluorescence from this state, to that of the laser excited resonance fluorescence as the laser frequency is changed. Phillips and Pritchard (*Phys Rev Lett*, **33**, 1254, 1974) have proposed that this technique should give velocity resolutions comparable with that obtained

using the crossed molecular beam method, providing that the target is at least five to ten times heavier than the atom or molecule excited. They also suggest that since the velocity distribution in the laser experiment is known exactly, the true cross section can be deconvoluted from the measured one very accurately, so that this compensates for the slightly poorer velocity resolution of the laser experiment. It is proposed that, in some circumstances, state selection can be achieved by the use of a polarised laser beam. This should give a preferential orientation of either the orbital angular momentum vector, or of an electric dipole moment, along the direction of propagation of the radiation. The experiments described above are for the linear absorption region.

An alternative method of studying energy transfer that has already been demonstrated utilises saturation effects produced in low pressure gases by high power lasers. Under these conditions 'holes' are produced in the population of energy levels associated with the absorbing transition. Good examples of this type of behaviour are provided by the elegant double resonance experiments carried out by Freund, Johns, McKellar and Oka (*J chem Phys*, **59**, 3445, 1973). They studied two, three and four level systems in the vibration rotation spectrum of ammonia. The main effects that they demonstrated were the monitoring of a hole in the population of a vibration-rotation energy level caused by a strong two-photon pumping source, by a weak two-photon signal source, and the observation that holes burnt in the population of one level could be transferred to other levels by collisions. Two-photon pumping is not an essential requisite, and can be replaced by tunable laser sources once these become available. By fine tuning both the pumping and the monitoring sources different velocity molecules were studied, and by larger variations of the monitoring source energy transfer to different rotational energy levels was studied. Thus from one type of experiment it is possible to obtain information about both the magnitude of the intermolecular interaction $V(r)$ from the translational changes, and the angular dependence of the intermolecular interaction $V(\theta, \phi)$ from the rotational changes.

These sorts of study are only possible when the predominant cause of spectral line broadening is the Doppler effect, as in the infrared and visible regions. In the microwave region the lines are predominantly pressure broadened and double resonance then gives information only on rotational state changes, but not on changes in translational energy.

review article

Recent advances in electrical recording from the human brain

D. Regan*

New techniques for recording evoked potentials to sensory stimulation have led to applications with both theoretical and practical implications. Evoked potentials can be used as a diagnostic tool in some pathological conditions, as well as shedding light on the mechanisms by which sensory information is processed in the brain.

A FLOW of visual information to the eyes, auditory information to the ears or tactile information to the skin is represented by nervous discharges whose information content is successively reorganised as the signals pass from neurone to neurone on their way to visual, auditory or somatosensory areas of brain cortex where yet further processing takes place. The weak electrical currents generated here pass through the skull and can be recorded in the form of voltages, known as evoked potentials (EPs), between electrodes held on to the scalp. Although evoked potentials are generated mainly in the cortex, they can be used as tools to study the ways in which the brain sequentially processes sensory information as it ascends from peripheral to successively more central sites through the nervous system. They can also be used to reveal parallel processing in the brain, in which different types of information are handled simultaneously in separate channels.

During the past decade, descriptions of the ways in which single neurones in animal brains respond when the sensory end organ is stimulated have become a major influence in originating models of sensory information processing, and in this way have prompted a great many psychophysical studies designed to test the extrapolation of single-neurone studies to human perception. It is a long way from the electrical activities of nerve cells in cat or monkey brain to human conscious perception, and EP recording offers a promising means of bridging this interspecies gap. A second, quite different strength of EP recording is that it offers access to certain activities of both the normal and diseased brain that do not intrude into consciousness and so cannot be directly studied by psychophysics or subjective sensory tests. A third area in which EPs offer unique possibilities is in the objective testing of sensory function, especially in young children.

It is rare for a single sensory stimulus (for example one clap of the hands) to produce an EP so large and free from noise that it can clearly be seen in a normally amplified recording from scalp electrodes. More commonly the electrical activity of the rest of the brain is so prominent that the EP is buried in background noise. The most widely used method of enhancing the signal-to-noise ratio is signal averaging^{1,2}. An abrupt stimulus (for example a click) is repeated many (n) times, separated by intervals that are sufficiently long to allow the brain to settle down to its

undisturbed state between repetitions, and the n responses are electronically summed. If the EP to each stimulus is identical and occurs at exactly the same time after stimulation, the summed EP will be n times larger than a single EP, but the background noise will sum more slowly since it has no fixed relationship to the stimulus. This is called a transient EP because it is the transient response to an abrupt stimulus such as, for example, a brief flash of light, the

Fig 1 Evoked potential feedback when brain signals control the stimulus. The visual stimulus shown in the insert was a red pattern of bright and dark checks that exchanged places six times per second. Superposed on the pattern was a desensitising patch of light. The pattern elicited a 6-Hz evoked potential, whose amplitude continuously controlled the intensity of the desensitising light by means of a neutral density wedge in the desensitising beam. This feedback was set to maintain evoked potential amplitude constant at 6 μ V. When the colour of the desensitising light was changed from yellow to blue, the evoked potential immediately moved the wedge so as to increase the intensity of the desensitising light by about 40 times. Since the effect of the red (676 nm) pattern is restricted almost entirely to the red channel, this means that this channel is about 40 times more sensitive to yellow than to blue light. (Modified from Regan⁸)

Fig. 2 Pattern vision in cat and man compared by means of evoked potential recording. The filled squares are the "contrast thresholds" determined by evoked potential recording for three cats¹⁶. The open triangles are contrast sensitivities determined behaviourally for two other cats¹⁷, and closely agrees with the evoked potential data. The solid circles are contrast sensitivities measured in man¹⁶, where evoked potential and psychophysical estimates agree also. In comparison with the human curve, the cat's is displaced to lower spatial frequencies by a factor of about ten, a somewhat similar effect would result from viewing the world through reversed binoculars so that everything looked ten times smaller.

onset of steady illumination, or the cessation of a long train of rapidly-repeated clicks.

Steady-state EPs are quite different from transient EPs. When a rapidly repeated stimulus is switched on, there is first a transient response which then gradually settles down to a steady-state EP waveform that repeats at the same frequency as the stimulus (f Hz)³⁻⁵. Here, the stimulus is precisely defined in frequency rather than time so that the steady-state EP can be recognised in the midst of the brain's background noise since it is composed of components (harmonics) whose frequencies are exactly f , $2f$, $3f$ Hz and so on. A Fourier analyser can automatically carry out the required computations, display the amplitude and latency of the steady-state EP, and confirm that the EP fulfils the necessary condition of remaining constant from moment to moment throughout the recording^{3,4}.

In some studies transient and steady-state EPs give complementary insights into brain function. From a practical point of view the steady-state method has the advantage of speed (it is up to 100 times faster)⁷, which may be especially important in clinical studies.

Using Fourier analysis of the waveform, EP amplitude can be displayed as a moment-to-moment running average, thus providing feedback to the experimenter so that he knows at once what result he has produced by changing some stimulus parameter^{3,6}. A different way of utilising this feedback is to arrange that, by electronic means, the EP itself continuously controls the stimulus so as to maintain EP amplitude constant⁸⁻¹⁰. Then the experimental subject's experiences are slightly disturbing if he consciously tries to blur a stimulus pattern by defocusing his eye, the stimulator opposes him so that the pattern's visibility does not seem to change. The experimenter, however, obtains through this technique a direct measurement of EP sensitivity, instead of an indirect one through amplitude measurements, with the advantages of increased precision and much shorter experiments as, for example, in measuring approximations to the action spectra of the eye's colour mechanisms⁸⁻¹¹ (Fig. 1).

Experimenters searching for the neural basis of conscious perception have looked for relationships between psychophysical measurements of sensation and evoked potentials

in human subjects. In such experiments, evoked potential recording offers a bridge between the detailed subjective reports and quantitative measures of conscious perception that can be obtained from human subjects and the recordings from individual nerve cells in the brains and sensory pathways of animals.

For example, the logarithmic relationship that has been shown to obtain between the amplitude of EPs elicited by a sine-wave grating and the objective contrast of the grating^{12,13} corresponds to the logarithmic relationship between stimulus contrast and subjective perception of contrast^{14,15}. The relationship between contrast and EP amplitude has been extended to cats^{16,17} and followed up with studies on the effect of grating contrast on the firing frequencies of single neurones on the cat's visual pathway¹⁸. These experiments showed that the logarithmic relationship held for just one class of neurones, the so-called simple cells of the visual cortex, whose behaviour thus seems to provide a basis for stimulus contrast perception.

The question of whether EP generation fails when the stimulus is made just too weak to produce a sensation has attracted a good deal of attention. There have been encouraging early reports of the use of EPs to auditory stimulation in assessing the bearing of babies and infants¹⁹⁻²³, although some later reports have been less optimistic²⁴. A straightforward way to estimate EP threshold is to graph EP amplitude against stimulus intensity in coordinates that give a straight line plot, and then extrapolate to zero EP amplitude. This method has been used for auditory EPs¹⁹⁻²³, and for visual pattern EPs^{12,13,25,28,29} in both cases giving EP thresholds that agreed well with subjective (psychophysical) thresholds. This latter finding for pattern EPs complements earlier reports that EPs could not be evoked by stimulating an eye with pattern during periods when pattern vision through that eye was suppressed by interocular rivalry³⁰ or by interocular suppression³¹⁻³³.

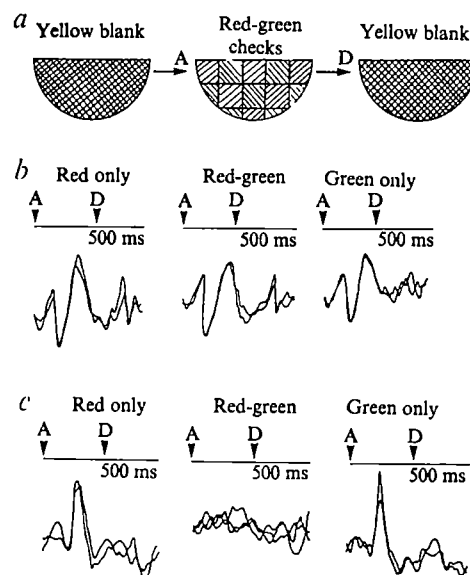

Fig. 3 Evoked potentials produced by a pattern defined only by colour differences. *a*, Stimulus: an unpatterned yellow patch abruptly changed to pattern of equiluminant red and yellow checks (appearance) and then back again (disappearance) without any change in total light flux. The traces marked red-green show that EPs to appearance (A) and disappearance (D) of pattern are clear in normal (*b*) but absent in colour blind (deuteranopic) subjects (*c*). The pattern of red-green checks is made up of a pattern of bright and dark red checks superposed on a pattern of bright and dark green checks. Traces marked red and green show that the constituent monochromatic patterns give clear EPs in both normal and colour blind subjects. (Modified from Regan and Spekreijse⁵²).

Fig 4 Pattern information is handled in parallel red and green channels which fuse before the stage of perception *a*, Red and green images cannot be simultaneously in sharp focus because of the eye's chromatic aberration, but when one or other image is momentarily sharp the corresponding colour channel feeds a strong signal to the gate, the function of which is to transmit preferentially the stronger pattern signal, possibly by means of inhibition between red and green pattern channels. Consequently it is the more sharply focused image that is seen at any given moment independently of whether it is the red or the green image, and furthermore beyond the gate the spectral sensitivity of the pattern channel is effectively photopic rather than being most sensitive to red or to green. *b*, Illustration of one possible arrangement of neuronal connections at the most peripheral stage. Excitatory signals shown by +, inhibitory by -. Uniform illumination by any colour gives zero final output. An output is, however, produced when a bright-dark boundary (or a red-green boundary) is positioned between the cone pairs. Note that this arrangement is by way of illustration only. Many other possible schemes of lateral inhibitory connection would also give sensitivity to spatial contrast borders.

Particularly for pattern stimulation, these findings offer an objective means of estimating psychophysical threshold in animals that may well prove important in future studies of the neural basis of sensation (Fig. 2). For example, such findings promise an alternative to the laborious behavioural methods in animals for detecting the effects on the visual pathway of an impoverished visual environment or artificial rotation of the visual world in early life.

It should not, however, be assumed that EP and psychophysical thresholds always coincide, even roughly. For example, flickering the intensity of an unpatterned patch of light gives EPs that bear no relation to subjective threshold. Whole experiments can easily be carried out with stimuli so weak that the subject never sees them³⁴. More significantly, the same increase of flicker frequency can increase EP amplitude, while abolishing the sensation of flicker^{3, 35}. This dramatic difference between EPs elicited by changing stimulus contrast (pattern) and by changing overall stimulus intensity is consistent with the suggestion that the two types of EP are generated by different populations of cortical cells³⁶.

In practice the two types of EP can easily be confused, since stimulating the eye with a pattern does not necessarily give a pattern EP. Although a fine pattern may give pure pattern EPs, a coarser version of the same pattern can give patterns responses mixed with EP components more or less similar to those elicited by flickering an unpatterned field^{29, 37, 38}. A curious consequence is that blurring a coarse pattern can increase the amplitude of pattern reversal though for fine patterns, as one would expect, blurring drastically attenuates the EP^{39, 40}. More recently it has been suggested that the second types of EP component produced by pattern reversal reflect the activities of movement detectors rather than luminance responses^{26, 41, 42}.

The original evidence for pattern detectors tuned to narrow ranges of spatial frequency in the human visual system was psychophysical⁴³⁻⁴⁵, now supported by evidence from EPs to sinewave grating stimuli which are sensitive to grating orientation and spatial frequency¹². Suggestions

based on psychophysical experiments that there exists a type of "feature filter", sensitive to an edge at some particular location in the visual field⁴⁶⁻⁴⁸ have been linked with the discovery of neurones in cat and monkey brains that are preferentially sensitive to light-dark boundaries in the visual field⁴⁹. Naturally, a sinewave grating covers a considerable area and also looks blurred at all times and would therefore not be expected to give EPs that emphasised the activities of local edge detectors. A pattern containing sharp edges, however, does elicit EPs that suggest some contribution from edge detectors. For example, EPs to a chequerboard pattern are almost abolished by occluding the edges of checks with very thin wires³⁷, and even very slight blurring markedly attenuates chequerboard EPs^{29, 32, 33, 40}, a result that, because of EP saturation, would not be expected if the effect of blur were caused entirely by contrast reduction⁵⁰.

Colour coding of pattern vision

A pattern that is defined only in terms of colour with no luminance differences can give clear EPs. For example a fine pattern of alternate equiluminant red and green checks or stripes elicits EPs when the red and green elements are interchanged^{27, 51} or when the pattern appears from a previously uniform yellow field⁵² (Fig. 3). Such EPs are markedly attenuated if the sharp edges of the bars or checks are even slightly blurred³³. These EPs are still large in the deliberately artificial situation when the eye's chromatic aberration is cancelled in such a way that both red and green images are sharply focused on to the retina⁵³. I have suggested that the existence of such EPs show that the physiological signals generated by red and green lights must still be segregated when they arrive at the most peripheral pattern-sensitive neurones in the eye (or brain). In other words, the most peripheral stage of pattern processing is

Fig 5 Spectral sensitivities for the red and green channels of pattern vision. The red channel (predominantly) was stimulated by a foveal red (676 nm) pattern of fine checks as in Fig. 1, and a desensitising patch of light was superposed on the red pattern. The intensities of the desensitising patch needed for a given attenuation of the red pattern EP were plotted (reciprocally) as ordinates against desensitising wavelength, giving the right hand curve. The experiment was repeated with a green (544 nm) pattern to obtain an approximation to the spectral sensitivity of the green channel (left hand curve). These spectral sensitivities approximate those of Stiles π mechanisms. Note because of the overlap of red and green spectral sensitivities, the colour channels are not completely separated by this technique (Modified from Regan⁹).

Fig. 6 *a*, Low, *b*, medium, and *c*, high frequency responses to flicker. The amplitudes of EPs produced by flickering an unpatterned patch of light show resonant-like peaks in three frequency regions. The properties of EPs are fairly uniform within a single frequency region, but are quite different in different frequency regions. EPs in the different frequency regions are generated in different areas of the brain, have different latencies, different colour properties and, furthermore, demyelinating disease slows medium frequency but not high frequency responses. The three types of signal may be separate from an early stage in the visual system. Note that these EPs to unpatterned flicker have quite different properties from EPs to fine patterns (whose frequency dependence is shown by dots) (Modified from Regan⁸⁶).

duplicated in parallel red and green-sensitive channels (Fig. 4). There is evidence that segregation is total⁵². In effect these channels treat a fine pattern defined in terms of different colours as though it were defined by differences in light intensity across borders. Thus, neural responses to fine patterns (for example checks smaller than about 20 arc min) can be explained without invoking opponent colour mechanisms.

In the case of fine patterns, an interesting effect occurs when the relative intensities of red and green checks are critically adjusted. The sharp borders between the checks become indistinct^{54,56}, particularly when the eye's chromatic aberrations are cancelled⁵³. Significantly, red-green edges are minimally distinct when red and green luminances are equal⁵⁴⁻⁵⁶. Nevertheless, EPs to fine patterns are large at the balance point and show no sign of a minimum^{26,27,53}. This suggests that the red and green pattern channels, although separate at the most peripheral stage, fuse before the stage of perception in such a way that the resulting single pattern channel has the eye's photopic spectral sensitivity (Fig. 4).

Here the charm of EP recording is that a neural organisation is clearly revealed even though its operation is not subjectively evident and does not intrude into perception.

One function of this peripheral colour segregation might be to minimise the degradation of visual acuity caused by the eye's chromatic aberration. Red and green lights from a pattern are never simultaneously in sharp focus on the retina, so that a pattern detector sensitive to a wide range of colours would always receive a blurred retinal image. If, however, the most peripheral stage were segregated into two colour channels, then at any moment either the red or the green channel would receive a more sharply-focused image and preferentially feed into the next stage (Fig. 4). This would explain why visual acuity has been reported to be little worse in white than in monochromatic light^{57,60}, why acuity for one colour can be unaffected by superposing light of a different colour^{61-64,66}, why the eye's depth of focus is greater in white than in monochromatic light⁶⁶, and would also be in accord with the McCollough effect⁶⁵.

This is not the whole story, however. There seem to be additional detectors in the human brain that take advantage of colour differences in such a way that we see spatial patterns more clearly⁵³. These detectors respond preferentially to borders between differently coloured areas. Unlike

the intensity-pattern detectors described above, they are sensitive to chromatic contrast *per se* and may involve opponent colour mechanisms. Their activity is more evident for coarse than fine patterns¹²³.

Evoked potentials to a pattern of equiluminant red and green checks are a sensitive test for colour blindness⁵², and can give some insight into the condition. For example in one colour blind (deuteranopic) subject, EP amplitude could be completely abolished by carefully balancing the intensities of red and green checks⁵² (Fig. 3), which suggests that ocular chromatic aberration was almost ineffective⁵³ and therefore only one colour channel is present. Indeed in a later study¹¹, measurements of the pattern channel's action spectrum showed that the deuteranope investigated had a red mechanism only.

Approximations to the action spectra for the red and green channels of human pattern vision, measured objectively by recording EPs elicited by a pattern of fine checks directed on to the fovea⁸⁻¹¹, are similar to the action spectra of red and green retinal photopigments or the red and green colour mechanisms of Stiles (Fig. 5). In these experiments EP recording has the advantage over psychophysical methods that approximations to action spectra can be straightforwardly measured, not only near the threshold of pattern perception, but also at high, everyday levels of pattern sensation and with very little added adapting light. The point here is that if intense adapting lights are used, the effect of either red or green cones will be selectively reduced by chromatic adaptation so that separate colour mechanisms will be observed even if red and green signals are not segregated at the contrast stage. Only if very little adapting light is used can it be confirmed that red and green signals really are segregated at all times.

The blue channel of pattern vision is not evident when the eye is stimulated with a blue pattern, even when the

Fig. 7 A patch of standard white light was alternated with a patch of blue light 24 times/s. The blue light's intensity was adjusted by the subject until he saw minimum flicker (arrowed, 2 on abscissa). At this point, therefore, the blue test light and standard white light had the same photometric luminance. The steady-state EP was composed of two frequency components: —, a medium-frequency component of 24 Hz and — — —, a high-frequency component of 48 Hz. The high-frequency EP component fell to a minimum close to the point of minimum subjective flicker (continuous line), so that its amplitude correlated with the photometric luminance of the blue light. In contrast, the medium-frequency EP component (broken line) showed no minimum and was large even when the light did not appear to flicker at all (at arrow). This component therefore did not correlate with photometric luminance. Other evidence shows that it correlates with stimulus colour. Note that the averaged waveform (*a*, *b* and *c*) arbitrarily confounded the two components and was virtually uninterpretable (Modified from Regan⁸⁴).

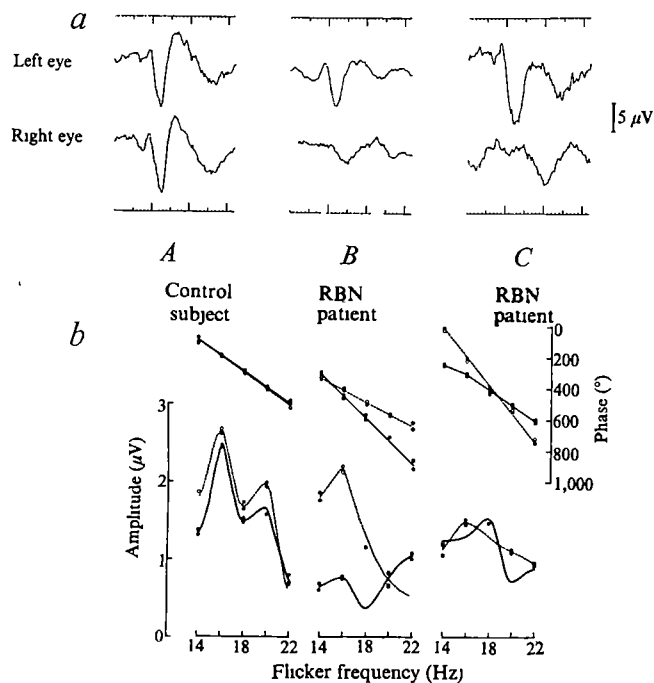

Fig 8 Delayed visual evoked potential in patient with multiple sclerosis *a*, Transient evoked potentials to pattern for a healthy subject (*A*) and two patients (*B*, *C*) who were recovering from acute attacks of retrobulbar neuritis in the right eye. Note the delayed and attenuated responses from the affected eyes. Time (abscissae) divided into 100, 50 and 10 ms (From Halliday *et al*⁸⁹) *b*, Steady-state evoked potentials elicited by flickering an unpatterned patch of light for a healthy control subject and for two retrobulbar neuritis (RBN) patients —, The right eye, — —, the left eye. Note that for the affected eyes the plots of evoked potential phase against flicker frequency are steeper than for the good eyes (that is, the evoked potential is delayed for the affected eyes). This can be seen to hold independently of whether amplitude is attenuated (From Milner *et al*⁸⁷)

checks are as coarse as 40', presumably because the blue mechanism is insensitive. It can be revealed by using intense yellow chromatic adaptation in the same way that Stiles isolated his blue π mechanisms (ref 67 and D R, unpublished observations). More precise measurements on colour blind subjects have recently shown, that the blue pattern channel's action spectrum approximates that of Stiles' blue π mechanism, even in the absence of chromatic adaptation¹¹.

The colour properties of pattern EPs described above are quite different from the colour properties of EPs elicited by unpatterned stimuli as described in the next section.

Unpatterned coloured stimuli

The aim of revealing differences between the ways in which the eye handles light of different colours has led several experimenters to compare EPs elicited by red, green, blue and yellow flashes. In experiments where different colours were reported to give different EP waveforms the stimulus fields seem to have been so large that they illuminated an inhomogeneous retinal region including rods as well as cones⁶⁸⁻⁷¹. In one crucial experiment stimulation was restricted to the fovea, a 2° central retinal area that is relatively homogeneous and mediates good colour vision⁷². This experiment did not support the notion that different colour sensations are associated with different EP waveforms, since red, yellow, green and blue flashes now gave transient EPs the waveforms of which were similar.

On the basis of EP latency rather than waveform Krauskopf was able to distinguish the separate contributions of red, green and (the slowest) blue chromatic mechanisms even when he used small (1°) foveal stimuli⁷³. Adapting Stiles' increment technique to EP work, Krauskopf used chromatic adaptation to select one or other chromatic

mechanism and obtained EP evidence that red, green and blue activities, separate at the most peripheral level, do not converge until at least 50 ms after stimulation. It has often been suggested that differences between the time courses of neural signals elicited by red, green and blue light may be the brain's physical representation of hue⁷⁴⁻⁷⁷. This notion might, perhaps, be open to test in man by further EP applications of Stiles' techniques for isolating colour mechanisms.

Although there seems to have been surprisingly little success in identifying EP correlates of the colour sensations aroused by monochromatic lights, the accompanying luminosity sensations seem to have clear EP correlates. Armington found that the amplitudes of some components of transient EPs to flash correlate with photometric luminance*, in other words they have the same spectral sensitivity as the light-adapted eye^{78,79}. Flickering an unpatterned patch of light gives steady-state EPs that are often composed of two frequency components, one at the flicker frequency and one at twice the flicker frequency. The two frequency components have quite different colour properties, provided that the frequency of one ("medium frequency") component falls in the range 13-25 Hz while that of the other ("high frequency") component fall in the range 35-60 Hz (Fig 6). The amplitude of the high frequency component can be used to measure the spectral sensitivity curve of the eye with rapidity and a precision quite equal to that of the conventional psychophysical method (better than 0.05 log unit)^{34,81}. This method has already been used in goldfish⁸² and promises a simple alternative to behavioural methods in the monkey.

Although this high frequency component of the EP therefore correlates with photometric luminance, the medium frequency component does not, even though it is part of the same averaged waveform (Fig 7). Medium frequency components do not even have a unique spectral efficiency curve⁸³, are very sensitive to chromatic adaptation^{81,84,85} and may reflect the activities of opponent colour mechanisms⁸⁶. The latencies of medium and high frequency EPs differ by about 2:1 (roughly 120 and 60 ms respectively)^{5,34,81,84,88}. High frequency and medium frequency EP components, carrying different visual information might well be anatomically separate, travelling along parallel channels, very early in the visual system (see below).

Clinical applications of evoked potentials

Two factors that initially prompted clinical application of EP recording were (1) the need for objective tests of sensory function in young children and babies where conventional ways of testing vision and hearing are uncertain, and (2) the failure of some EPs to correlate with sensation, which means that they offer access to some activities of sensory pathways not accessible to subjective tests. Both these possibilities have recently become practicalities, and it seems that indeed there are certain specific clinical diagnostic problems where custom-designed EP methods can usefully supplement conventional sensory tests.

One example is that of multiple sclerosis, in which breakdown of the insulating myelin sheath surrounding the axons (conducting fibres) of nerves eventually leads to impaired or blocked nervous conduction. This demyelination characteristically occurs at several sites in the central nervous system and multiple sclerosis can be difficult to diagnose when there is evidence of demyelination at only one site. This problem can be eased by using recently developed EP tests that detect damage to the visual pathway caused by retrobulbar neuritis, a common precursor of multiple sclerosis.

* "Photometric luminance" is not quite the same as "brightness". Even when intensity (and therefore photometric luminance) is held constant, the brightness of patterned stimulus can be altered by manipulating the patterning⁸⁰. In this manoeuvre, EP amplitude correlates with photometric luminance rather than brightness⁴⁰.

- Transient EPs to pattern stimulation are significantly delayed in almost all patients after such an attack⁸⁹⁻⁹¹, steady-state EPs to pattern are also delayed^{87,88}. Flashing an unpatterned field, however, gives transient EPs that have been reported to provide no reliable indication of retrobulbar neuritis, though there is some disagreement on this point⁸⁹⁻⁹⁴. On the other hand flickering an unpatterned field elicits steady-state EPs that are reliably delayed in all patients for flicker frequencies in the medium-frequency region between 13 and 25 cs^{-1} (Figs 6 and 8)^{87,88}. The flicker test for retrobulbar neuritis has the advantage over the pattern test that it can be used even when the patient's visual acuity is low. Curiously, flicker EPs were delayed for no patients when flicker frequencies lay in the high-frequency region between 35 and 60 cs^{-1} ^{87,88}. This difference is an example of the ability of EPs to provide information not accessible to sensory tests, since neither medium-frequency nor high frequency EP amplitude correlates with flicker perception^{3,6,26,35}. The difference might be explained if the two types of flicker signal travel along different classes of axons in the optic nerve, one of which is preferentially demyelinated.

In a few patients delays may reach 100–180 ms⁸⁷⁻⁹¹. Such large delays are difficult to explain entirely in terms of slowed conduction along myelinated nerve fibres^{87,88}.

In patients in whom, on clinical evidence, demyelination seems restricted to the spinal cord, a high percentage have delayed transient EPs to pattern, and this evidence of visual pathology has proved useful in diagnosing multiple sclerosis^{89-91,95}. Interestingly, when steady-state EPs are recorded the flicker and pattern tests may pick up different patients, suggesting that the two tests are sensitive to different aspects of visual damage caused by multiple sclerosis⁹⁵.

Refraction and amblyopia

Spectacles can be prescribed by recording evoked potentials to pattern, since the largest responses are produced when the pattern looks sharpest^{7,96-101}. As little as one minute's recording is required when the power of the test lens is varied continuously during the examination⁷.

The clinician faces a more difficult problem when his patient cannot see fine detail, but spectacle lenses fail to improve vision. In this condition (amblyopia) the visual defect seems to lie in the networks of nerve cells in the retina and brain that handle pattern information. It seems likely that a period in early life during which a distorted image of the world is formed on the retina can be a major cause of this abnormal neural development. Childhood squint, and uncorrected long sightedness in one eye only are common causes of amblyopia¹⁰²⁻¹⁰⁴, uncorrected astigmatism can lastingly impair the ability to see straight lines of one particular orientation ("meridional amblyopia")^{106,107}. If allowed to persist until the child is too old, amblyopia becomes irreversible and the child may be left with only one good eye. During early childhood amblyopia can be cured by simple treatments such as by occluding the good eye for a period, normal vision then gradually returns to the amblyopic eye¹⁰²⁻¹⁰⁴. Accurate estimates of the patient's visual acuity are clearly important for effective treatment. Unfortunately it is during early childhood, the time when treatment is most effective, that reliable estimates of visual acuity are most difficult to obtain, especially in realistic conditions where several different retinal regions are simultaneously stimulated^{102,104}. Recording EPs to patterned stimuli offers a means not only of studying the mechanism of amblyopia but also of estimating the visual acuity of young children, and thus of improving treatment of amblyopia^{108,113} including meridional amblyopia^{7,114,115}.

There is disagreement whether stimulating the amblyopic eye's fovea gives normal EPs^{107,109-112}, but it does seem clear that the retinal area immediately surrounding the fovea (perifovea) give larger EPs for the amblyopic than

for the good eye¹¹⁰⁻¹¹². When fovea and perifovea are stimulated together (as in everyday life) foveal responses are relatively depressed¹¹⁰⁻¹¹² suggesting that different retinal regions interact abnormally. EPs from amblyopic and good eye are inverted in polarity, and this difference disappears after successful treatment¹¹².

If EP recording is to become a practical way of testing vision in young children it must be developed into a much briefer test. A speedy method developed with this in mind is to project on to a screen a checkerboard pattern whose dark and bright squares exchange places six times per second while slowly zooming up and down in size once every 30 s. The 6-Hz EP to the pattern is continuously plotted against check size, and several such graphs are electronically averaged. The child's attention is maintained during the 2–3 min required by projecting a cartoon film on to the checked pattern¹¹³.

Where binocular vision seems normal it is now possible to test stereoscopic depth vision objectively, since EPs can be recorded that are specific to changes in binocular disparity (that is, to movements in depth)^{116,117}.

Abnormal visual projections in albinos

In many animals including man the projection from each eye is divided so that signals from the right half of each retina go to the right hemisphere of the brain, and from the left hemiretina to the left hemisphere. Guillery and others have found that, in the albinos of several species, signals from a patch of retina near the midline are erroneously routed to the opposite hemisphere, so breaking up the orderly left-to-right projection of the retinal image on to the cortex¹¹⁸⁻¹²². Guillery has suggested that the squint commonly found in these albinos may be a functionally useful adaptation to this misrouting.

Evoked potential recording offers one means of testing whether visual signals from part of the retina are routed to the wrong side of the brain in human albinos. When an albino subject viewed a visual stimulus with one eye only, the resulting EP seemed to be generated in one rather than both hemispheres^{123,124}. Although it is difficult to carry out visual EP tests on albinos with nystagmus, these results do indicate that EP recording offers a means of finding whether any patient with defective vision might have an underlying abnormality in the routing of his retino-cortical connections.

I thank many research workers who allowed me to read unpublished manuscripts, Mr R. F. Cartwright for technical assistance, and the Medical Research Council for support.

Surface reactivity of tungsten

R. P. H. Gasser & G. V. Jackson

Physical Chemistry Laboratory, South Parks Road, Oxford OX1 3QZ, UK

Pre-adsorbed nitrogen or β -carbon monoxide inhibit the surface reactivity of tungsten towards hydrogen, both in catalysis and in adsorption. The effect of nitrogen can be satisfactorily accounted for by a simple reduction in the area of reactive filament, taking into account the selective adsorption of this gas by the low index planes of tungsten. With carbon monoxide the effect is considerably greater, perhaps because of lateral interactions between adsorbed hydrogen and carbon monoxide.

ISOTOPE equilibration reactions taking place on the surface of a metal are among the simplest examples of heterogeneous

catalysis and thus provide a suitable starting point for investigating in detail the catalytic process. One particularly attractive feature of the study of these reactions is the excellence of the agreement observed between experiments carried out on polycrystalline wires of quite different origin¹⁻⁶. In addition to the intrinsic interest of such studies, it is possible to use the equilibration reaction as a chemical probe to investigate the surface. Thus, when a tungsten wire was used as a catalyst for nitrogen, carbon monoxide or hydrogen isotope equilibration^{4,6,7} it was found that poisoning by pre-adsorbed oxygen was nearly linearly dependent on the fractional oxygen coverage. From this it was inferred that active patches⁸ did not form a significant part of the surface. Furthermore, combination of the results of these experiments with measurements of the adsorptive characteristics of the surface (the saturation uptake and the initial

sticking probability) shed light on the close, yet elusive, relationship between the centres of catalysis and chemisorption. Some further evidence on this point has come from studies of the catalytic activity of the low index planes of tungsten [(100), (110), and (111)] in ammonia decomposition⁹, in which it was reported that the activities of the planes were different, as are their reactivities towards nitrogen¹⁰.

Because nitrogen and carbon monoxide are both more strongly bonded in their β states to polycrystalline tungsten than is hydrogen, these gases might be expected to inhibit the activity of tungsten as a hydrogen isotope equilibration catalyst. If this were to happen it would then be possible to compare the effects of a dissociated-molecule inhibitor¹⁰ (N_2) with the probably, though not certainly, undissociated carbon monoxide¹⁰⁻¹². It is this comparison we report here.

Measuring catalytic activity

The same apparatus was used as for the earlier experiments⁴. It consists of a Pyrex glass ultra-high vacuum (UHV) chamber ($p_{\text{min}} < 5 \times 10^{-10}$ torr) in which the experimental filament (length 20.7 cm and geometric area 0.83 cm^2) is suspended. The filament had been cleaned previously by extensive heating in oxygen and its reactivity was monitored regularly during the present series of experiments, by observing the uptake and initial sticking probability of nitrogen. The constancy of these quantities during the course of the work was taken as sufficient evidence that the filament did not become contaminated. Flashing to about 2,040 K *in vacuo* sufficed to remove adsorbed gases and was the normal method of cleaning.

The experimental gases were admitted through all-metal valves from either of two gas storage volumes. Adjustment of the apertures of these valves produced the required partial pressure of a gas. A similar valve connecting the UHV chamber

to the pump controlled the rate of flow of a gas over the filament. Partial pressures were measured with an omegatron radio-frequency mass spectrometer which formed part of the UHV section. A commercial Bayard-Alpert ionisation gauge (Edwards High Vacuum) with a low temperature, lanthanum hexaboride-coated rhenium filament was used to calibrate the mass spectrometer. The catalytic activity of the filament was measured by streaming a mixture of approximately equal partial pressures of hydrogen and deuterium over it and observing the formation of HD at the expense of H_2 and D_2 .

The efficiency E of the filament as an equilibration catalyst has been defined previously⁷ by the ratio

$$E = \frac{\text{Observed rate of production of HD}}{\text{Maximum possible rate of production of HD}}$$

The way in which the heights of the mass spectrometer peaks, recorded under steady state conditions, are used to calculate E

Fig 3 Effect of pre-adsorbed nitrogen or carbon monoxide on s_0 of hydrogen (\circ or \bullet) or deuterium (Δ or \blacktriangle). Uptakes of nitrogen or carbon monoxide as in Fig 1.

Fig 2 Inhibition of hydrogen isotope equilibration at elevated temperatures by adsorbed nitrogen (800 K) and by adsorbed carbon monoxide (690 K). Symbols as in Fig 1.

has been fully described elsewhere⁷. Earlier experiments have shown that E is independent of pressure within the range 2×10^{-7} – 9×10^{-7} torr (ref. 7), and a total pressure between 5×10^{-8} and 6×10^{-7} torr was used in these experiments. The catalytic inhibiting effect of pre-adsorbed nitrogen or carbon monoxide was investigated as follows. The filament was cleaned and cooled to room temperature *in vacuo*. Nitrogen or carbon monoxide was then let in and the filament was allowed to adsorb for the appropriate time. After cutting off the gas supply the filament was heated briefly to 650 K to equilibrate the adsorbed layer and to remove any gas in the weaker α state¹¹. The hydrogen–deuterium mixture was then streamed over the filament at a chosen temperature and when the peak heights of masses 2, 3 and 4 were constant they were recorded. Contamination of the filament by the background gas (largely CO) presented more of a problem in this work than it had done previously, because it was not possible to flash off impurities accumulated from the background without disturbing the initial layer. This difficulty was particularly marked with CO which is reversibly adsorbed by the walls of the UHV chamber^{13,14}. The experimental time for measurements of catalytic activity at any particular coverage was thus limited to about 0.5 h. After the measurements had been made the uptake of carbon monoxide was determined by heating the filament in stages, to 650 K to remove the hydrogen and, when the gas had pumped away, to 1,610 K to desorb carbon

monoxide. A record of the pressure burst caused by this desorbed gas was made with a rapid-response amplifier and ultraviolet recorder, from which record the uptake was calculated. Nitrogen uptakes were calculated from the partial pressure record, made with the omegatron, during the initial adsorption¹⁵.

The effects of pre-adsorbed nitrogen or carbon monoxide on the adsorptive characteristics of the filament, as defined by the initial sticking probability s_0 and the maximum uptake θ_{H_2} at a pressure near 1×10^{-7} torr, were determined in a separate series of experiments. To do this the filament was partially covered as before and hydrogen or deuterium was admitted at a constant rate from a storage volume. The partial pressure during the adsorption period was recorded with the omegatron until the filament was saturated. s_0 and θ_{H_2} were both calculated from this record¹⁵.

The effects of the two gases on the efficiency at room temperature are shown in Fig. 1 and in the plateau region⁷ (690 K for CO, 800 K for N_2) in Fig. 2. Within a set of experiments carried out under fixed conditions the relative values of E are consistent, though the absolute accuracy is not better than $\pm 25\%$ (ref. 7). The ways in which s_0 and θ_{H_2} depend on the uptakes of CO or N_2 are shown in Figs 3 and 4.

Implications

The discussion of these results and their relationship to the earlier observations of the effect of pre-adsorbed oxygen atoms on the surface reactivity of this filament towards nitrogen, hydrogen and carbon monoxide gives an opportunity of reviewing the conclusions that can be drawn from experiments of this type about the chemical constitution of the surface. In so doing it is appropriate to relate the work, where possible, to the conclusions drawn from other techniques. But, in view of the proliferation of papers relating to the surface of tungsten the comparison must be selective.

We shall take as the starting point for discussion a consideration of the relevant geometric factors. Tungsten has the b.c.c. structure and it has been suggested that a well annealed polycrystalline filament will expose predominantly the (100) and (110) planes^{16,17}. As far as the influence of nitrogen on the catalytic efficiency is concerned, this suggestion provides an immediate interpretation of the considerable remaining catalytic activity of the nitrogen-saturated filament, roughly half that of the clean filament, because nitrogen adsorption on tungsten shows a strong surface-plane dependence. A careful review of the evidence reached the conclusion that dissociative chemisorption occurs on W(100) at room temperature, but that the W(110) plane is unreactive¹⁰. Subsequent experiments have either confirmed this conclusion^{18,19} or have demonstrated that, at most, adsorption takes place with a sticking probability which is initially very low (0.005) and which thereafter declines rapidly²⁰. On the other hand hydrogen shows no such geometric sensitivity and adsorbs readily and extensively on a polycrystalline tungsten filament^{7,16,21,22} and on both of these single crystal planes²³⁻²⁶. The catalytic activity towards hydrogen of the nitrogen-free surface can thus be attributed to both (100) and (110) planes. Saturation with nitrogen then removes the reactive sites on (100) planes but leaves the (110) planes clean and still reactive.

The near-linear decline in efficiency with increasing nitrogen uptake is closely paralleled by the fall in s_0 and θ_{H_2} . In this, the effect of nitrogen closely resembles the way in which the first stage of oxygen adsorption reduces the activity of this filament towards hydrogen (though oxygen will eventually eliminate all reactivity) and the results can be interpreted (as for O-atom adsorption) as the consequence of a reduction in the area of reactive surface directly proportional to the uptake of the pre-adsorbed gas. The similarity between oxygen and nitrogen extends further, in that for both gases the reactivity is halved by a coverage of about 2.7×10^{14} atoms cm^{-2} . But, whereas for nitrogen all the atoms are on the (100) plane, the non-selective adsorption of oxygen by tungsten²⁷⁻²⁹ presumably leads to a

Fig. 4 Effect of pre-adsorbed nitrogen or carbon monoxide on maximum room-temperature uptake of hydrogen (O or ●) or deuterium (Δ or ▲). Uptakes of nitrogen or carbon monoxide as in Fig. 1.

distribution of oxygen atoms over both the (100) and (110) planes. It is interesting to note that this chemical similarity between adsorbed oxygen and nitrogen is reflected in the formation of ordered geometric arrangements, as detected by LEED (low energy electron diffraction), of the atoms of both gases on the (100) plane^{30,31}.

There are two previous experiments concerned with the co-adsorption of nitrogen and hydrogen on tungsten which are of particular relevance to this work^{21,32}. These experiments were principally concerned with the uptakes resulting from sequential adsorption of nitrogen and hydrogen and with the ability of nitrogen to replace previously adsorbed hydrogen on either a polycrystalline wire²¹ or a W(100) single crystal plane³². The major conclusion drawn from both of the earlier experiments, and one with which the results presented here are in complete accord, was that there is very little interaction between adsorbed hydrogen and adsorbed nitrogen.

We now turn to a consideration of the effect of pre-adsorbed carbon monoxide on the reactivity of tungsten. The method used for preparing a surface partially covered with CO ensured that the gas was held in the more strongly bonded of the surface states of CO on tungsten, the β states, the α -CO having been desorbed by the prior heating to 650 K (ref. 33). The β state is itself composite and consists of three substates, normally called β_1 , β_2 and β_3 in ascending order of binding strength. As expected these were poorly resolved under the conditions of our experiments¹⁴ though with special care separation is possible³³. In adsorption, the β_2 and β_3 states fill up first so that the early part of the catalytic inhibition curve is associated with the poisoning effect of carbon monoxide in these states. As Figs 1 and 2 show $(\beta_2 + \beta_3)$ -CO has a profound effect on the reactivity of tungsten, an uptake which is only about 40% of β -CO saturation reduces E by about 90%. This uptake has a comparable effect on s_0 and θ_{max} as Figs 3 and 4 show. It is thus clear that a CO molecule is much more effective at deactivating the surface than either an oxygen atom or a nitrogen atom. This observation again agrees very satisfactorily with the earlier measurements of the co-adsorption of carbon monoxide and hydrogen^{21,34}. The more recent of these studies showed that adsorption of CO weakened the bonding of hydrogen to the surface (in this case the (100) plane) thereby generating a new state which was desorbed at 273 K but which was retained on the surface at lower temperatures. A fractional coverage of CO equal to 0.4 was sufficient to exclude all β -hydrogen from the surface at 273 K. Bearing in mind that this observation relates to a monocrystalline surface and the results in Figs 1-4 are for a polycrystalline surface, the concordance between the two sets of experiments is striking. It has been pointed out, however,

that the characteristic desorption spectrum of β -CO from tungsten can be accounted for satisfactorily starting from the postulate that carbon monoxide adsorption takes place dissociatively and that lateral, repulsive interactions are present between the adsorbed atoms³⁵

The initial purpose of this series of experiments was an attempt to locate the sites of catalytic activity on a tungsten surface. There seems to be little doubt that for the reactions chosen to probe the surface, which probably come into the category of 'facile'³⁶, much of the surface which is capable of adsorbing the gases is also catalytically active. It will be interesting to discover whether this is also true of more complex reactions.

We thank the Science Research Council for an equipment grant and for a studentship for G. V. J.

The nucleotide sequence of an RNA polymerase binding site on bacteriophage fd DNA

K. Sugimoto, T. Okamoto, H. Sugisaki & M. Takanami

Institute for Chemical Research, Kyoto University, Uji, Kyoto, Japan

The nucleotide sequence of the RNA polymerase binding site at a promoter on fd RF DNA has been determined in comparison with the starting sequence of RNA initiated at this promoter. The RNA polymerase binding site contained the startpoint of transcription in the centre and a region with twofold symmetry in the non-transcribed part.

SEVERAL species of RNA with unique starting sequences and sizes are transcribed on the doubly closed replicative form (RF-I) DNA of fd bacteriophage¹. This suggests that fd RF-I DNA provides sets of specific sites for initiation and termination of transcription. To analyse the structure at such an RNA initiation site (promoter), we first constructed the cleavage map of RF-I DNA using *Haemophilus* restriction endonucleases, and then localised the promoters on the map. We found that a short DNA segment, Hap-Hga V, contained one of the promoters for G-start RNA (Fig. 1), the fragment representing about 3.8% of the length of fd DNA and corresponding to about 230 base pairs. A uniform RNA of about 120 bases long was efficiently synthesised on this fragment. The DNA fragment was specifically bound to RNA polymerase with GTP present. As the binding of the polymerase to DNA renders the covered portion of the DNA resistant to DNase^{2,3}, the region protected by the polymerase was isolated from Hap-Hga V. We compared the nucleotide sequence of the polymerase binding site isolated in this way with the sequence of RNA initiated on Hap-Hga V, based on the transcription of the DNA sequence into RNA in the oligonucleotide-primed reaction⁴.

Preparation of fd RF-I DNA, *E. coli* RNA polymerase, and restriction endonucleases (*Hap* and *Hga*) from *H. aphrophilus* and *H. gallinarum* was as previously described^{3,5}. For preparation of Hap-Hga V, a complete digest of RF-I DNA with *Hap* and *Hga* was prepared⁵, mixed with RNA polymerase and GTP, DNA fragments which formed stable complexes with the

polymerase were isolated as in the legend to Fig. 2b. The two fragments (Hap C and Hap-Hga V in Fig. 2b) isolated by this

Fig. 1 The location of Hap-Hga V on the cleavage map of fd DNA. The map has been constructed using the cleavages with *Hap*, *Hga* and *Hind* (a restriction endonuclease from *H. influenzae* Rd). Hap A,B — and Hga A,B ---- label of fragments created by *Hap* and *Hga* (our unpublished observations). Hap-Hga V is produced either by digestion of Hap D with *Hga* or by digestion of Hga A with *Hap*. The G-start RNA initiated on Hap-Hga V proceeds in the counter-clockwise direction and terminates at a site on Hap C.

Fig 2 Gel electrophoretic patterns of (a) a digest of fd RF-I DNA with *Hap* and *Hga*, (b) DNA fragments which bind to RNA polymerase with GTP present, (c) RNA synthesised on Hap-Hga V, (d) a partial T₁ RNase digest of RNA made on Hap-Hga V, (e) the RNA polymerase binding site isolated from Hap-Hga V, and (f) (A)₃ U-primed RNA formed on the polymerase binding site. (a) A complete digest of ³²P-RF-I DNA with *Hap* and *Hga* was layered on a 5% polyacrylamide gel column (0.6 cm × 12 cm), electrophoresed for 12 h at 2 mA per tube, and the autoradiograph was taken as in ref 5. (b) The Hap-Hga digest of ³²P-RF-I DNA (0.1 mg) was added to a binding mixture (3 ml) containing 8 mM MgCl₂, 50 mM KCl, 40 mM Tris (pH 7.9), 0.1 mM GTP, and about 100 pmol RNA polymerase. After 20 min at 30°C, the mixture was passed through a Millipore filter (HA 0.45 μm). The filter was washed with 1 M KCl, 8 mM MgCl₂, 20 mM Tris (pH 7.9) and then with 8 mM MgCl₂, 20 mM Tris (pH 7.9). DNA fragments retained on the filter were eluted with 0.2% SDS–20 mM Tris (pH 7.9). The eluate was deproteinised, concentrated and electrophoresed as in (a). (c) Hap-Hga V (non-labelled, about 2 pmol) was added to a reaction mixture (1 ml) containing 8 mM MgCl₂, 50 mM KCl, 40 mM Tris (pH 7.9), 0.1 mM dithiothreitol, 0.1 mM α-³²P-GTP (10⁷ c.p.m./nmol), 0.2 mM each of three other nucleotide triphosphates, and about 10 pmol RNA polymerase. Incubation for 30 min at 37°C was terminated by shaking with 80% phenol. The aqueous layer was passed through a Sephadex G50 column (1 cm × 30 cm). The RNA fraction was collected, and electrophoresed on a 15% gel column for 3 h at 150 V as in ref 7. Under these conditions, about 7 pmol of RNA were synthesised. Arrow shows position of 5S ribosomal RNA as marker. (d) ³²P-RNA synthesised on Hap-Hga V was partially digested with T₁ RNase as in ref 6, and the digest was electrophoresed as in (c). The numbered bands were extracted, rerun on 15% gels containing 7 M urea, and submitted to sequence analysis. (e) Hap-Hga V (labelled with ³²P, about 20 pmol) was added to the binding mixture given in (b). After 10 min at 30°C, 50 μg of DNase I were added and incubation was continued for an additional 30 min. Digestion was terminated by shaking with 80% phenol. The aqueous layer was treated with ethylether, dialysed against 0.1 mM EDTA–20 mM Tris (pH 7.9), and electrophoresed on a 15% gel as in (c). (f) The portion of Hap-Hga V protected from DNase I digestion (about 4 pmol) was heated for 5 min at 100°C, rapidly cooled, and added to a reaction mixture (1 ml) containing 8 mM MgCl₂, 50 mM KCl, 40 mM Tris (pH 7.9), 0.1 mM dithiothreitol, 10 μM α-³²P-GTP (5 × 10⁷ c.p.m./nmol), and 20 μM each of three other nucleotide triphosphates, 10 μM AAAU, and about 10 pmol of RNA polymerase. Incubation was carried out for 3 h at 37°C, and terminated by shaking with 80% phenol. After removal of phenol with ethylether, the template was digested with DNase I. The solution was deproteinised, and passed through a Sephadex G50 column. The RNA fraction collected was mixed with 50 μg of fd SS DNA. NaCl was added to 0.9 M and sodium citrate to 0.09 M. The mixture was heated for 5 min at 100°C, held for 3 h at 51°C, slowly cooled, and passed through a Millipore filter. The filter was washed with 0.3 M NaCl, 0.03 M sodium citrate. RNA retained on the filter was dissociated by heating for 5 min at 100°C in 20 mM Tris (pH 7.9), and electrophoresed on a 15% gel column containing 7 M urea, as in (c).

Fig 3 Two-dimensional fingerprints of T₁ RNase digests of (a) RNA synthesised on Hap-Hga V, and (b), (c) (A)₃ U-primed RNA formed on the RNA polymerase binding site. (a) (*G) RNA was synthesised on Hap-Hga V as in the legend to Fig 2c and digested with T₁ RNase. The digest was applied to a 20 cm × 20 cm PEI-cellulose plate and chromatographed as in ref 6. The sequences of the spots numbered are given in Table 1. (b) and (c) (*G) RNA was synthesised on the heat-denatured RNA polymerase binding site and fractionated as in the legend to Fig 2f. Bands 1 and 2 indicated in Fig 2f were digested with T₁ RNase and chromatographed as in (a). (b) Fingerprint of Band 2. (c) Fingerprint of Band 1. The sequences of spots numbered are given in Table 2.

procedure were separated by sucrose density-gradient centrifugation. On adding Hap-Hga V to an RNA synthesising mixture, a uniform RNA which migrated near 5S ribosomal RNA as marker was efficiently synthesised (Fig 2c). The RNA only hybridised to the (–) strand of the template, like those made on intact RF-I DNA. For isolation of the RNA polymerase binding site, Hap-Hga V was mixed with RNA polymerase and GTP, digested with DNase I and the portion protected was isolated as in the legend to Fig 2e. The gel electrophoretic pattern of the polymerase binding site prepared by this procedure is shown in Fig 2e. The average chain length estimated from the analysis of the terminal P was roughly 45. To synthesise RNA on this fragment, the fragment was denatured by heating, and incubated in an RNA synthesising mixture containing a primer oligonucleotide. The synthesised RNA was isolated, and fractionated by hybridisation to fd single-stranded (SS) RNA [(+) strand]. The RNA fraction complementary to fd SS DNA was collected, and further resolved by gel electrophoresis (Fig 2f). The detailed conditions for RNA synthesis and the procedure for fractionation of RNA are given in the legend to Fig 2f. Hydrolysis of RNA with RNases and analysis

of the digests by two-dimensional chromatography on PEI (polyethylenimine)–cellulose plates were as described previously⁶

Sequence of RNA synthesised

RNA was synthesised on Hap-Hga V with each of the four nucleoside α³²P-triphosphates (abbreviated as (*N)RNA, where N = A, C, G, or U), and hydrolysed with either pancreatic RNase or T₁ RNase. The resulting nucleotides were resolved on PEI–cellulose plates. A typical fingerprint obtained from (*G)RNA is shown in Fig 3a. The distribution of ³²P in each spot was determined. In addition, the nearest neighbour analysis was carried out on each spot after the complete digestion with T₂ RNase. All the nucleotides obtained and their approximate molar ratios are summarised in Table 1.

The sequence of shorter oligonucleotides was determined simply by the distribution of ³²P in nucleotides. For analysis of longer oligonucleotides, each digestion product was further cleaved using either pancreatic RNase or T₁ RNase, and chromatographed. The products were digested with T₂ RNase, and ³²P in nucleotides determined. The sequences for all the

* The products obtained from (*C)RNA are listed

† Nucleotide linked to the 5'-end is underlined

‡ The position of C in parentheses is not determined by the nearest neighbour analysis

Fig 4 The nucleotide sequence of RNA synthesised on Hap-Hga V. The region covered by each partial T_1 RNase product is underlined. The numbers represent the bands indicated by the side of Fig 2d. Each band has been repurified using gel electrophoresis in urea.

oligonucleotides were determined in this way, except those for spots T10, T16, T18 and T19 in the T_1 RNase digest. The nearest-neighbour analysis of T10 deduced four possible sequences, CAUCCUAG, CCUAUCAG, CCAUCUAG, and CUAUCCAG. As the nucleotide linked to the 3'-end is G, we looked for three possible sequences, GCA, GCC and GCU, in the pancreatic RNase digest. Table 1 shows only one GCU in P2c and two GCA in P2a and P5. As two GCA appear in T4a and T12 in the T_1 RNase digest, we concluded that the sequence for T10 is CUAUCCAG. The analysis of T16 deduced two possible sequences, UCAUUCUCG and UCUCAUUCG. The sequence was determined to be UCAUUCUGG by digestion with U_2 RNase. Two alternative sequences were also obtained for T19, AAUAUUUAUG and AUUUAAUAUG. Two possible sequences, GAAUA and GAUU, were looked for in the pancreatic RNase digest. There are three GAUU in P12a and one GAAUA in P13. The three GAUU appear in T9, T14 and T15 in the T_1 RNase digest. Thus the sequence for T19 was deduced to be AAUAUUUAUG. The nearest-neighbour analysis did not provide information on the position of C in the U cluster of T18. This sequence has been determined to be UUUUCUG in a separate experiment, in which the sequence of RNA formed on the (+) strand of Hap-Hga V in the oligonucleotide primed reaction was analysed. The sequences of most oligonucleotides in Table 1 have also been confirmed by this type of analysis.

To reconstruct RNA from the T_1 RNase products, partial T_1 RNase digests were prepared and resolved by gel electrophoresis (Fig 2d). The resulting bands were redigested with

reduced RNA synthesis was stimulated approximately threefold by adding $(A)_3U$ as primer. We chose this oligonucleotide as primer because RNA formed on Hap-Hga V contained the sequences, AUUU and AUUUUU, near the starting end (see Fig 4).

RNA was synthesised with each of the four nucleoside $\alpha^{32}P$ -triphosphates, fractionated by hybridisation to fd SS DNA, and resolved by gel electrophoresis. Note that the direction of RNA thus prepared is the reverse of the RNA made on 'intact' Hap-Hga V. The major band obtained (Band 2 in Fig 2f) was digested with T_1 RNase and chromatographed on PEI-cellulose plates. A typical fingerprint obtained from $(^*G)RNA$ is shown in Fig 3b. The major spots detected are listed in Table 2. The amounts of spots T1 to T5 were about equimolar. The sequence of each spot was analysed as in the previous section. For analysis of longer oligonucleotides, digestion was carried out using either pancreatic RNase or U_2 RNase. Unique sequences were obtained for all spots, except for T5. The sequence deduced for T5 was U(CUU)UACCCUG, in which the position of C in parentheses was not determined. Spots T6 and T7 contained AAAU at the 5'-end and overlapped with the sequence at the 3'-end. These sequences are just complementary to the sequence which either positions 9 to 15 or positions 9 to 22 on the RNA made on Hap-Hga V (see Fig 4). In addition, the sum of T6 and T7 was about equimolar with each other spot (see Table 2). Thus, we concluded that the leftward RNA analysed had been initiated with primer at either position 15 or position 22 on the sequence in Fig 4. On the basis of analysis on nucleotides adjacent to the terminal G, all the

Fig 5 The nucleotide sequence of the RNA polymerase binding site on Hap-Hga V. The starting sequence of RNA formed on Hap-Hga V is indicated for comparison. The region with twofold symmetry is underlined. The axis of symmetry is at the -10 position.

T_1 RNase and chromatographed on PEI-cellulose plates. On the basis of the result obtained and information on the nucleotide adjacent to the terminal G of each spot, all the T_1 RNase products were ordered into a sequence of RNA, except those for the region between the positions 84 and 104 (Fig 4). The arrangement of three segments in parentheses is not determined yet. The yield of P17(GGAAU) which was assigned to the 3'-end of the RNA was less than one mole in the pancreatic RNase digest (see Table 1). This suggests that the RNA chains were randomly terminated after position 120.

Sequence of RNA polymerase binding site

As shown in Fig 2e, the fraction of Hap-Hga V which was protected from nucleolytic digestion by the polymerase binding gave a relatively uniform band on gel electrophoresis. To analyse the sequence of such a region, the DNA fragment isolated was denatured by heating and added to an RNA synthesising mixture in which the substrate concentration was

T_1 RNase products obtained can be ordered either (1) T6(T7) T1 T4 T5 T3 T2 or (2) T6(T7) T1 T5 T4 T3 T2. The combination was determined as (2) using the analysis of Band 1 in Fig 2f. Band 1 is assumed to be an intermediate, as this band was shifted to the Band 2 region by extending the incubation period. On chromatography of the T_1 RNase digest of Band 1, the major spots detected were only T1, T5 and T6. In Fig 3c, a fingerprint obtained from $(^*G)RNA$ is shown. Note that spot T1 is only obtained from $(^*U)RNA$. In other experiments, T7 was also detected in addition to these three spots. According to this combination, the sequence subsequent to T6(T7) becomes complementary to the starting sequence of RNA made on Hap-Hga V.

In Fig 5, the sequence of RNA finally deduced is shown as the sequence of DNA. The sequence has been confirmed by the analysis of the pancreatic RNase products (Table 2). The sequence would represent only the major part of the polymerase binding site. Nevertheless, the size of the sequence determined was about equal to the average size of the DNA fragment isolated as the polymerase binding site. Figure 5 shows that the

right half of the sequence is just identical with the starting sequence of RNA initiated on Hap-Hga V, indicating that transcription is initiated in the centre of the binding site. The other feature of the sequence is that a region with twofold symmetry is contained in the non-transcribed part, as indicated in Fig. 5. Such symmetrical regions have been detected in the polymerase binding site of other promoters^{8,9}, although each sequence is different. Initiation of transcription would include at least the processes of recognition of the promoter signal and formation of an initiation complex by the polymerase. If these processes occur at different parts of a promoter, the polymerase binding site we analysed would be a part of the promoter. As mentioned earlier, RNA chains are efficiently initiated on Hap-Hga V indicating that this fragment contains all of the sequence information needed for the promoter function. The length of the non-transcribed region of this fragment is about 100 base pairs. Sequencing of such a region will provide more information about the feature of the promoter.

In the course of this study, we learned that Schaller, Gray and

Herrmann¹⁰ have determined the sequence of a strong RNA polymerase binding site on fd by direct DNA sequencing. The sequence obtained by these authors coincides with the sequence of the polymerase binding site presented in this paper. They also note a region with strong symmetry in the non-transcribed part of the binding site.

We thank Dr Schaller for the exchange of unpublished information.

letters to nature

Radiation as a source of gravitation

I HAVE investigated a few steady state cases according to general relativity, and some of the results are of interest.

Throughout this letter, relativistic units ($c = 1$, $G = 1$), and ray optics are used.

(1) Spherical symmetry, purely radial rays. The metric is

$$ds^2 = e^{2\nu} dt^2 - (1 - 2\Phi)^{-1} dr^2 - r^2(d\theta^2 + \sin^2\theta d\psi^2) \\ \nu = \nu(r), \quad \Phi = \Phi(r) \quad (1)$$

Imposing $T = T_2^2 = T_3^3 = 0$ and defining

$$4\pi r^2 T_0^0 = -4\pi r^2 T_1^1 = \varepsilon(\Phi)$$

the equations reduce to

$$\frac{d\varepsilon}{d\Phi} = \frac{2\varepsilon}{1-2\Phi} \frac{\Phi + \varepsilon}{\Phi - \varepsilon}, \quad \frac{1}{r} \frac{dr}{d\Phi} = -\frac{1}{\Phi - \varepsilon}, \quad \varepsilon e^{2\nu} = \text{constant} \quad (2)$$

Note that ε , a pure number, is the sum of the equal inward and outward fluxes of radiation, and that, for comparison, the

outward flux of the Sun is $\varepsilon = 10^{-26}$, while a quasar might perhaps reach 10^{-4} .

The solutions of equation (2), in the relevant region ($\Phi < \frac{1}{2}$, $\varepsilon \geq 0$) can be expressed in closed form in terms of $x = (\frac{1}{2} + \varepsilon)[\varepsilon(1 - 2\Phi)]^{-1/2}$. They start at the origin along $\varepsilon = \Phi$ (Fig. 1) (region A) then sharply slice off towards the right, proceed towards higher values of Φ with an only imperceptibly increasing ε (assumed to be fairly small) (region B) until, shortly before $\Phi = \frac{1}{2}$ is reached, ε begins to grow rapidly, with Φ soon passing a maximum and then diminishing (region C), while ε still grows. The line $\Phi = 0$ is crossed, and ε grows until $\varepsilon = -\Phi$ whence (region D) $\varepsilon \rightarrow 0$ as $\Phi \rightarrow -\infty$. Note that the origin corresponds to $r = \infty$, that the radius drops very sharply along the curve in region A, quite fast in B, but only gently as we proceed through C and D with $r \rightarrow 0$ as $\Phi \rightarrow -\infty$.

It is immediately plain that our normal picture of such a system is represented by A and the adjacent parts of B, and that C and D are the unexpectedly peculiar neighbourhood of the centre where focusing produces a curious singularity, probably irreproducible in practice owing to the non-zero wavelength of light.

To avoid the centre, radiation may be limited to $r \geq r_1$ by putting a material body in. Most simply, if at $r = r_1$ there is a thin material shell with positive T and T_0^0 and empty interior, then necessarily

$$0 < \Phi_1 < 4/9, \quad \varepsilon_1 < \frac{1}{2}[1 - (1 - 2\Phi_1)^{1/2}][3(1 - 2\Phi_1)^{1/2} - 1] \quad (3)$$

so that we are confined to regions A and B. The zone of radiation may also be terminated by an outer shell, with empty space beyond. Though the conditions are a little more complex than at an inner shell, in fact the radiation pressure helps to support the shell.

Without an internal body, the central conditions do not select any particular solution of equation (2). Indeed the central singularity is such that on this ray picture it should be possible to confine, by an external shell, the zone of radiation to C and D, and even to terminate it with Φ so negative that, even with the necessarily positive mass of the shell, the external solution is one of negative mass.

Fig. 1 Schematic diagram of a typical solution of equation (2)

(2) As a second example, one could treat this case in a quasi-Newtonian fashion by taking the flux ϵ to be constant. Therefore the energy content and thus supposedly the mass would depend linearly on the radius, being proportional to it if the radiation extends to the centre. In this last case the potential Φ would equal ϵ and be constant throughout (corresponding to region *A* above), in the more general case of a central body of mass exceeding that of its volume filled with appropriate radiation $\Phi - \epsilon$ would be a positive multiple of r^{-1} (corresponding to region *B* above), whereas there seems to be no relativistic case corresponding to a central body with mass less than that of its volume filled with the continuation of the radiation.

Note that metric (1), with $\Phi = \text{constant}$, $rdv/dr = \text{constant}$, leads to a non-trivial constant energy tensor T_{μ}^{α} which, for small equal and opposite values of the constants, gives radial radiation in the first approximation.

(3) Cases of cylindrical symmetry. These may be static or stationary depending on whether the fluxes parallel to the positive and negative z directions are everywhere equal or not.

Consider now a static case characterised by an amplitude A and apply a Lorentz transformation of velocity V parallel to the z axis. The flux against V will be enhanced and that in the opposite direction diminished. Now let $V \rightarrow 1$, while letting $A \rightarrow 0$ suitably. In the limit one arrives at a system with a unidirectional flow of energy. Unidirectional cases so derived form a special class (which of course could have been derived directly) with the property that all rays are parallel to the axis. The existence of this class is somewhat surprising since after all the stream of energy near the axis should act as a source of gravitation leading to rays weaving in and out, crossing each other along the axis of symmetry and being pulled back from further out by the gravitational force, as is indeed the case in general for cylindrically symmetrical systems.

With the appropriate general metric (all coefficients are functions of r only)

$$ds^2 = e^{2\sigma} [e^{2\lambda} \cos 2\gamma dt^2 + 2 \sin 2\gamma dt dz - e^{-2\lambda} \cos 2\gamma dz^2] - e^{2\delta} dr^2 - r^2 d\psi^2 \quad (4)$$

this particular class is given by

$$\delta = \sigma = 0, \quad w(\gamma) \equiv r d\gamma/dr = \pm r \cos 2\gamma d\lambda/dr$$

giving

$$8\pi T^{00} = \frac{e^{-2\lambda}}{2r^2(\pm 1 - \sin 2\gamma)} \frac{d}{d\gamma} (w^2 \cos^2 2\gamma)$$

naturally with the trace of the energy tensor and its radial and transverse components vanishing.

(4) More generally, acceptable solutions of equation (4) representing pure radiation without transverse (ψ) components are described by equation (4) in the notation $u = r d\sigma/dr$, $v = r d\lambda/dr$, $w = r d\gamma/dr$ by

$$\delta = 2\sigma,$$

$$2rdu/dr = 2u + u^2 - v^2 \cos 2\gamma + w^2 \geq 0,$$

$$rdv/dr \cos 2\gamma \geq 4vw \sin 2\gamma,$$

$$(rdv/dr \cos 2\gamma - 4vw \sin 2\gamma)^2 \geq (rdu/dr)^2 + (rdw/dr - 2v^2 \sin 2\gamma \cos 2\gamma)^2$$

equality in the last case implying unidirectional flow of energy. Full details will be published elsewhere.

Spectra of the Jupiter radio bursts

BETWEEN March and September of 1973 and 1974, observations were made of the Jupiter radio bursts with the Llanherne filled-aperture low frequency radio telescope¹ (650 m \times 650 m). The signals over the frequency range 4–29 MHz were recorded directly on to six video tape recorders for 5 min each day near transit. Some observations at 15–17 MHz were also obtained between May and September 1972. Frequency-time spectra were subsequently made with a 256-channel real-time analyser with channels 10 kHz wide and separated by 10 kHz. The spectra were recorded on 35-mm film moving at a variety of speeds from 150 inch min⁻¹ to 3 inch min⁻¹. When records with higher frequency resolution (2 kHz) or time resolution (100 μ s) were required, a time expansion spectrum analyser² with 1,500 channels in a 3 MHz bandwidth was used. Over the observing period, tape records of the Jupiter radio bursts were obtained during about two-thirds of all transits, and so far about 80 h of video tape containing the bursts has been accumulated. Here I present a preliminary description of the chief properties of their spectra.

Like the solar radio bursts, the dynamic spectra provide a convenient basis for classification, and the existence of at least two classes, the L bursts with a time scale of seconds and the S bursts with a time scale of milliseconds, has been recognised by earlier observers^{3,4}. But with the better time and frequency resolution now available it has become clear that there is considerably more variety in the radio phenomena as well as much more fine structure.

The L or lane bursts are seen on the frequency-time ($f-t$) plane as a diffuse background crossed by drifting modulation lanes (Fig. 1*a*). The ($f-t$) slope is ~ 0.2 MHz s⁻¹. Rùhima³ has identified several subclasses of L bursts on the basis of the sign of df/dt , which may be positive or negative or both. The slope is a function of the system III longitude of Jupiter and the modulation is therefore likely to be associated with the emission and propagation of the radiation near the planet. The lanes are quasi-periodic in time with a period of about 3 s near 21 MHz and are observed from 8 to 30 MHz (ref. 3).

Other types of lane structure have been seen in the present observations. When the time scale is expanded by a factor of 10, a second class, the fast lane (FL) bursts, is observed in which the ($f-t$) slope of modulation is near 2.0 MHz s⁻¹ (Fig. 1*a*). Again, both positive and negative $f-t$ slopes are observed. The quasi-period of the modulation is approximately 30 ms. FL bursts were observed between 5 and 17 MHz on 29 out of 56 occasions on which Jupiter bursts were recorded between April 22, 1973, and July 2, 1973. Within this frequency range they have the unusual property that the $f-t$ slope of the modulation lanes is independent of frequency (Fig. 2). At still higher time resolution a third class, the very fast lane (VFL) bursts, was observed on a few occasions both

Fig. 1 Dynamic spectra of Jupiter radio bursts. *a*, Lane bursts and fast lane bursts, *b*, very fast lane bursts, *c*, shadow drift pair burst, *d*, S bursts, *e*, U burst.

Fig. 2 Observed variation of df/dt with wave frequency for S bursts and fast lane bursts. Solid lines show the theoretical variation for cyclotron radiation from electrons of speed $0.1c$ travelling in the Io L shell for different values of equatorial pitch angle ϕ_0 . Magnetic field dipole moment $4 \text{ G } R_J^3$. a, $\phi_0 = 2^\circ$, b, $\phi_0 = 2.16^\circ$, c, $\phi_0 = 2.5^\circ$.

in the 14–17 MHz and 4–7 MHz frequency ranges (Fig. 1b). The f - t slope is approximately 15 MHz s^{-1} and is again independent of frequency between 16 and 4 MHz s^{-1} . The quasi-period of the modulation lanes for these bursts is near 4 ms.

A separate class of bursts, the shadow drift pairs, is illustrated in Fig. 1c. A typical spectrogram shows a pair of parallel dark bands with a mean separation in time of 0.4 s and a mean f - t slope of 1.4 MHz s^{-1} . They bear a remarkable resemblance to the solar radio drift pair bursts, except that they are seen in absorption rather than emission. Like these latter bursts, their properties vary only over a small range. Ten examples were recorded in July and August 1972.

Short, or S, bursts with a single frequency duration of 1 to 10 ms were observed during about half the Jupiter radio events between April and July 1973 (Fig. 1d). Their f - t slope is 10 MHz s^{-1} at 12 MHz, and is very nearly proportional to the wave frequency over the frequency range 5 to 15 MHz (Fig. 2). Their instantaneous bandwidth is typically 10 kHz, although it may be as small as 3 kHz. These measured values of df/dt are likely to be too high by approximately 0.008 MHz s^{-1} if account is taken of the effect of the analyser bandwidth⁵ on the variable frequency signal. Within the millisecond time scale of the S bursts, there are many fine structure phenomena which resemble those seen in the terrestrial vlf emissions. Triggered and periodic bursts occur frequently, and there is much evidence of wave-particle interactions from sudden changes in f - t slope where S burst spectra cross constant frequency emissions. On a few occasions, S bursts with reverse (positive) f - t slope are observed. A rare variant of the S bursts is the U burst, or inverted U burst, which shows a quasi-parabolic change and reversal in f - t slope (Fig. 1e). U bursts have been seen so far only below 10 MHz. Like the shadow drift pairs, the f - t spectra of the U bursts resemble those of the corresponding solar radio emissions, the solar U bursts.

The distribution of f - t slopes of all these bursts is shown in Fig. 3, where three main regions near 0.1 MHz s^{-1} , 1.0 MHz s^{-1} and 10 MHz s^{-1} may be seen. Similar groupings of df/dt exist for the solar radio emissions. So far no satisfactory explanation of the lane bursts has been advanced, although it has been suggested by Rùhímaa³ that the modulation results from interference between waves from multiple sources. The invariance of df/dt with f seems difficult to account for by this process. Rùhímaa also proposed, alternatively, that the lane structure is caused by the passage of the radiation through a moving spatially periodic screen after emission. Since different frequencies would be generated at different points along a field line, the frequency interval between the modulation lanes would be determined by the spatial period.

The properties of the S bursts, on the other hand, were predicted from a consideration of the likely radio emission from moving sources travelling outwards along the Jupiter magnetic field lines and radiating in the doppler shifted cyclotron mode⁶. As in the Earth's magnetosphere, the sources may be convective instabilities in almost monoenergetic electron streams⁷ or possibly isolated bunches of electrons as in the solar corona. The f - t slope is then a measure of the speed v of the source, and for a simple dipole field

$$df/dt \propto f^{4/3} A(\lambda, \lambda_m) v$$

$A(\lambda, \lambda_m)$ is zero for magnetic latitude $\lambda = 0$ or λ_m , the mirror latitude. If the magnetic dipole moment and the L shell of the electrons can be assumed, then their velocity and equatorial pitch angle ϕ_0 can be obtained from observations of df/dt over a sufficiently wide range of f . Figure 3 compares the observations with the calculated variation of df/dt with f for $v = 0.1c$ and $\phi_0 = 2^\circ$, 2.16° , and 2.5° respectively for electrons in the L shell of the satellite Io (Jupiter dipole moment assumed⁸ to be $4 \text{ gauss } R_J^3$). The mirror-point cyclotron frequency of the electrons is 38 MHz. It should be noted that if the maximum magnetic field cyclotron frequency fH_m near the planet's surface proves to be less than this, then this result may imply that the electrons are accelerated near the surface⁹. Two alternative revised models of the magnetic field⁸ derived from Pioneer 10 observations give $fH_m = 31$ and 38 MHz respectively. But fH_m is very strongly dependent on the precise location of the dipole centre and further revisions can be expected in the future.

Fig. 3 Distribution of frequency-time slopes of a, lane bursts, b, shadow drift pairs, c, fast lane bursts, d, S bursts, e, very fast lane bursts. Frequency range 15–17 MHz.

The S bursts do not normally extend in frequency over more than 1–2 MHz and do not individually exhibit the variation of df/dt with f shown in Fig. 1d. Indeed, the f - t trace may be curved in either direction, not just linear. The relatively small frequency range would be expected if the radiation is from sources travelling along curved field lines and strongly beamed as expected for cyclotron radiation. Slight variations in the speed of convective beam instabilities would account for the f - t deviations. The very narrow spread in the distribution of df/dt for observations made at different times is particularly striking and contrasts, for example, with the wide distribution for type III solar bursts. It points to a source of radiating electrons of almost constant energy such as has been suggested for the model of Goldreich and Lynden-Bell¹⁰, where the satellite Io acts as a unipolar inductor and a source of constant e.m.f. across the Io flux tube as it moves through the Jupiter magnetic field.

This investigation has been supported financially by the Australian Research Grants Committee

Alternative hypothesis for the origin of CCF xenon

I SUGGEST that the anomalous xenon isotopic composition known as carbonaceous chondrite fission (CCF) xenon is not caused by fission, but is the direct result of a modified r-process nucleosynthesis which produces an abundance peak at $Z = 54$ and the magic neutron number $N = 82$. I further propose that the xenon so produced ('R xenon') was trapped in dust grains, which were subsequently incorporated in the solar system with minimal degassing. This hypothesis also provides a natural explanation for the intimate association between R xenon and a newly discovered xenon component in primitive meteorites^{1,2}.

Analyses of the abundance and isotopic composition of xenon in meteorites have provided insight into several aspects of the early solar system and the origin of some of the complex patterns are now well understood. Recently, for example, it was confirmed that xenon in Ca-rich achondrites arises, in part, from the spontaneous fission of extinct ²⁴⁴Pu (ref 3).

One of the more enigmatic xenon compositions is found in carbonaceous meteorites and unequilibrated ordinary chondrites⁴, both of which are thought to be primitive meteorite types. It has properties which are characteristic of xenon produced from fissioning nuclides, hence its name, the CCF component.

It is still not clear whether this component actually has a fission origin, at least to the extent that the parent nuclide has not been identified. In order to identify the parent nucleus, the isotopic composition of the meteoritic xenon component must be compared with known fission spectra. Lack of identification could once have been attributed to a paucity of experimental data on fission spectra from nuclei in the mass range $240 \leq A \leq 260$, but this is not now the case⁵. A comparison of all presently known fission spectra with the meteoritic composition does not, however, yield any match (D C B, unpublished).

Failure to identify the hypothetical parent of the xenon component has not given rise to alternative interpretations but, rather, has generated more exotic suggestions as to the parent⁶.

Anders and Heymann⁶, and more recently Takaoka⁸, have shown that the amount of R xenon in a meteorite correlates with the abundance of trapped ¹³²Xe. This correlation is generally interpreted as a statement that the 'parent' nuclide which fissioned to give rise to R xenon was a volatile element⁶. There are, however, other interpretations, which I shall discuss later. The calculated absolute abundance of R xenon depends on the assumed trapped xenon isotopic composition, but is generally characterised by ¹³⁶Xe concentrations of $\sim 0.1 \times 10^{-10}$ to 1.0×10^{-10} cm³ STP g⁻¹.

Fig 1 Schematic representation of the abundance curves expected from 'classical' r-process (—) and s-process (---) nucleosynthesis in the mass range $120 \leq A \leq 150$. Data from ref 20

The most recent estimate (ref 9 and R O Pepin, private communication) of R xenon is given in Table 1. This estimate differs from previous ones^{10,11} primarily in that the ¹³²Xe/¹³⁶Xe ratio is lower (0.22 compared with 0.37) but is within the uncertainties associated with the earlier estimates. The new estimate agrees with that given by Marti¹² for ¹³⁶Xe, ¹³⁴Xe, ¹³²Xe.

As pointed out by Phinney¹ and Manuel *et al*², analyses of xenon isotopic compositions evolved from carbonaceous meteorites during stepwise heating experiments reveal the existence of an isotopically distinct xenon component which is characterised by a progressive enrichment (¹²⁴Xe > ¹²⁶Xe) in the isotopes of xenon which are shielded from contributions by way of fission. These workers have shown that the new component ('P xenon') does not arise from *in situ* nuclear processes and that it seems to be fairly uniformly mixed with R xenon. Manuel *et al* designate the mixture of P xenon and R xenon as Component X. More recent studies¹³ indicate that P xenon may be present in most primitive meteorites. Manuel and his co-workers do not speculate in detail as to the origin of P xenon, but they do suggest that P xenon and R xenon 'result from a common source'. In this regard, it is worth noting that Phinney attributes P xenon to p-process nucleosynthesis.

There is increasing evidence that some of the particulate matter (dust grains) in the primitive solar nebula were not heated sufficiently to degas quantitatively or chemically equilibrate with the bulk of the nebula, and have retained in part the elemental and isotopic characteristics of a period which predates the formation of the solar system. I shall designate such isotopic compositions as 'non-solar'. The first evidence was the discovery of a singular neon isotopic composition in carbonaceous meteorites¹⁴, characterised by a trapped ²⁰Ne/²²Ne ratio ≤ 3.4 , which was suggested to be 'non-solar'¹⁵. Subsequently, analyses of oxygen isotopic ratios in carbonaceous meteorites have led to the discovery of an isotopic anomaly which has also been described as 'non-solar'¹⁶. Work by Gray and Compston¹⁷ and Lee and Papanastassiou¹⁸ has revealed the

Table 1 Isotopic composition of R xenon

^{131}Xe	^{132}Xe	^{134}Xe	^{136}Xe	Ref.
—	0.28	0.71	$\equiv 1.0$	12
0.17 ± 0.02 -0.03	0.22 ± 0.07 -0.02	0.71 ± 0.01	$\equiv 1.0$	9 and R O Pepin, private communication

presence of magnesium isotope anomalies, again in carbonaceous meteorites, which, too, have been interpreted as being 'non-solar'. Theoretical models of primitive solar nebulae¹⁹ and the collapse of rotating protostars (D C B and P Bodenheimer, to be published) indicate that at heliocentric distances $\gtrsim 1.5$ AU, nebular temperatures would not have been sufficient to degas quantitatively interstellar dust grains present in the primitive nebula. Thus, the available evidence indicates that a fraction of the solid matter in the early solar system retained the elemental and isotopic compositions characteristic of their place of formation.

Generally, r-process nucleosynthesis is imagined to imply the rapid addition of neutrons to nuclei to synthesise elements beyond the iron peak. Typically, one is concerned with neutron densities $n_n \sim 10^{24} \text{ cm}^{-3}$ and temperatures $\sim 10^9 \text{ K}$. Under such conditions, the time scale for the addition of neutrons, $\tau_n = (n_n v_T \sigma_n)^{-1}$ where v_T is the mean thermal speed of the neutrons at temperature T and σ_n is the capture cross section of a given nucleus for neutrons, is much less than the time scale (τ_β) for β^- decay of the nucleus. In this situation, equilibrium is established between (n, γ) and (γ, n) reactions, with β^- decay providing a small perturbation or 'leakage' to the equilibrium established by the neutrons and photons. Such a picture leads to an abundance curve with a peak at mass 130 (ref 20), shown schematically in Fig 1. The peak is associated with a magic number ($N = 82$) of neutrons.

Fig. 2 Relative abundance ($^{136}\text{Xe} = 1$) of the xenon isotopes ^{134}Xe , ^{132}Xe and ^{131}Xe . a, b, Curves for r-process and s-process, respectively, obtained by renormalising those in Fig 1 so that their abundance peaks occur at mass 136, rather than mass 130 and 138 respectively. c, Composition of R xenon.

In the other limit, $\tau_\beta \ll \tau_n$, nucleosynthesis (s-process) proceeds along the valley of β -stability. Again, one finds that the effect of the closure of shells containing magic numbers of neutron appears in the form of a peak in the abundance curve at 82 neutrons and a mass of 138 amu (ref 20) (Fig 1). Note that both abundance peaks are steep and smooth because of the smooth variations in nuclear properties near the magic number of neutrons.

Figure 2 shows the abundance curves one would expect if the r-process and s-process peaks occurred at $A = 136$ rather than $A = 130$ and 138 respectively. The curves are normalised so that $^{136}\text{Xe} = 1$. Also shown is the abundance curve defined by R xenon. The R xenon curve falls between r-process and s-process abundance curves at all isotopes. If the r-process was altered to give rise to a peak at $A = 136$, it would be steeper than the plotted r-process abundance curve. In the limit, it must converge to the s-process abundance curve. Thus on a qualitative basis, the isotopic structure of R xenon is consistent with an r-process nucleosynthesis which produced an abundance peak at $A = 136$.

The physical condition required to shift the r-process abundance peak to larger values of A is basically that τ_n be increased. This allows the β^- decay to proceed further up the magic neutron ladder, at $N = 82$, than is the case for the 'standard' r-process nucleosynthetic chain. In fact, ^{136}Xe lies on the β^- decay ladder at $N = 82$ and is the first stable nucleus encountered by the ladder. The increase in τ_n can be brought about by lowering n_n and/or T . Preliminary estimates of the range in n_n and T required suggest a low density, high temperature regime such as one might encounter in a shock wave traversing the atmosphere of a supernova precursor.

It has been suggested²¹ that many of the p-process (proton-rich) nuclei are created in a supernova shock. If so, an intimate mixing of p-process nuclei and R xenon might result. The newly discovered evidence for such a mixing in carbonaceous meteorites would be a natural consequence of the modified r-process hypothesis.

One might expect manifestations of the modified r process in other elements. In particular, effects should be seen at three of the isotopes of krypton, namely ^{86}Kr , ^{84}Kr , and ^{83}Kr . As with ^{136}Xe , ^{86}Kr is the first stable nucleus encountered by a β^- decay ladder at a magic neutron number ($N = 50$). The magnitude of the attendant krypton effect cannot be estimated without more detailed calculations.

The abundance ($\text{cm}^3 \text{ STP g}^{-1}$) of R xenon does not lead to any particular problem (as is the case for the fission hypothesis). Assuming that the concentration of ^{136}Xe (R xenon) in dust grains is similar to typical xenon concentrations in meteorites ($\sim 10^{-8} \text{ cm}^3 \text{ STP g}^{-1}$), only $\sim 1\%$ of the material in carbonaceous meteorites need contain R xenon to explain the observed bulk abundance data. The correlation of ^{136}Xe (R xenon) with trapped ^{132}Xe would be expected if dust grains which contain R xenon mix with varying amounts of dust grains formed in the solar nebula. A similar correlation exists between trapped ^{36}Ar and the singular neon component discussed previously¹⁵, and has been interpreted in the same manner as the ^{132}Xe R xenon correlation^{15,22}.

Perhaps the most obvious future theoretical effort would be to vary the r-process nucleosynthesis parameters to give rise to an abundance peak at ^{136}Xe , and compare the resulting spectrum with that of R xenon. It is likely that requiring the abundance peak to occur at ^{136}Xe is a necessary, but not sufficient constraint on the nucleosynthetic calculations. One would like to determine the sensitivity of the calculated spectrum to variations in the controlling physical parameters (T , n and so on). If, within the uncertainty in the calculated spectrum, agreement is obtained between the experimental and theoretical spectra, one would like to know the astrophysical environment, or range of environments, likely to engender R xenon. In this connection, will the same environment(s) give rise to P xenon?

The experimental data available to date have primarily come

from stepwise heating experiments on bulk samples. This type of experiment provides a quantum jump over simple bulk analysis in the detailed knowledge one obtains from a sample. The state of the art now, however, requires a further quantum jump in information content per experiment, namely stepwise heating experiments on various discrete mineral phases or assemblages from a meteorite. It would seem particularly important to do rare gas analyses of at least neon and xenon in a given sample, and to have oxygen and magnesium isotope analyses done on aliquots of the rare gas samples. The questions are: do R xenon, neon E (ref 15) and the oxygen and magnesium isotope anomalies occur together, with what frequency and in what minerals? Are P xenon and R xenon well mixed, and if so is it on a microscopic scale (individual mineral phases and/or grains) or a macroscopic (in bulk) scale?

I thank Drs A G W Cameron, R O Pepin and D L Phinney for stimulating conversations

The beginning of a new cycle of solar activity

ON November 15, a high latitude sunspot marked the beginning of a new cycle of solar activity. The present cycle is on the decline and is approaching its minimum, a new cycle thus starting before the old one has completely disappeared. At this time the sunspots belonging to the old cycle originate near the equator, whereas those of the new one occur at higher latitudes.

The latitude of the sunspot observed was +37°, and it was 60° from the central meridian. It could be seen clearly the following day but not on November 17, when it crossed the western limb. The first spots of a new cycle usually appear more than a year before the coming minimum, so because the present activity is still relatively high, the minimum cannot be expected to occur before 1976.

Mathematical prediction of climatic change

A WIDESPREAD and increasing degree of attention is being paid to the problem of understanding the physical factors which lead to climatic change. Analysis of past weather data¹ derived from a wide variety of sources has shown how the main characteristics of climate have changed over recent centuries. If, however, scientific theories are to be developed, it is desirable that mathematical models of climate be constructed. These must include at least the primary global scale dynamics of the atmosphere and should allow the operation of necessary long time-period integrations on available computers.

The primary physical factor responsible for initiating the stirring of the atmosphere into its ever changing assembly of the cyclonic waves and anticyclonic systems is the meridional distribution of solar radiation, $S(\theta)$, where θ is the latitude. The response of the atmosphere to a given $S(\theta)$ and to the associated requirement of balancing the heat budget is seen in the continuously created train of weather systems which strive to rectify the imbalance, these systems are important agencies in determining climate. The sensitivity of climate to changes in solar radiation or changes in atmospheric transparencies should, therefore, be investigated.

In approximate calculations Budyko² used a system of empirical equations describing an assumed static balance (in a temporal sense) between the residual vertically integrated and zonally averaged annual radiation heating at a given latitude and the vertically integrated meridional flux divergence of heat. He assumed that his empirical heating functions were still valid when the total solar radiation was altered by a series of small percentages. An iterative computer procedure allowed Budyko to calculate the associated shift in the meridional distribution of mean atmospheric temperature, atmospheric and surface albedo, and the new mean, zonally averaged, simulated ice edge position. The primary atmospheric physics on a global scale is contained in Budyko's model (although rather crudely) but he assumed a static atmospheric balance, purporting to represent an asymptotic, annual average situation, corresponding to a prescribed solar heating, and there is no indication of how sensitively the calculated results depend on the mathematical forms of the empirical functions used. Consequently, his main result, suggesting that a 1.5% reduction in incoming solar radiation (or an equivalent change in atmospheric transparency) would lead to a new ice age, has met with scepticism. An extended form³ of the calculation has indicated that as much as a 5% reduction in solar radiation would be needed before large scale movement of the ice edge would occur.

These simplified static calculations, however, tell us nothing about time variations around the mean values of the large scale structure of atmospheric dynamics, indeed it may be completely incorrect to assume a stable balance of the averaged flow system for a perturbation of solar heating greater than some

Fig 1 Position (latitude) of the zonally averaged simulated ice edge as a function of time over a 200-d period. a, Solar heating values representing the present decade; b, a 3% reduction in solar heating.

critical value. For example, with small reductions in solar heating the zonally averaged ice-snow edge in the model may oscillate about its mean latitudinal position with a small spatial amplitude, as in a dynamically stable state, but with larger reductions the amplitude may become larger and there may occur a progressive movement towards the equator of the zonally averaged snow-ice position.

We have developed a time-dependent mathematical numerical model containing only the global scale dynamics, which simulates observed oscillations of the total atmospheric eddy kinetic energy associated with variations in the intensity of cyclonic systems. Basically, it is a modification of that introduced by Phillips⁴, and used⁵ in studies of the dynamics of anticyclonic blocking. The effects of standing waves on the planetary scale created by mountain barriers are not included and the effects of heating and friction in the model are taken as zonally averaged over continents and seas. The heating function, however, is not fixed geographically, as in the previous model, but is dependent on model atmospheric temperature, and a surface thermal balance equation is used, which predicts model surface temperatures. The very long time period integrations essential to theoretical studies of climate are practical from a computing point of view: only 10 min computing time is required to carry out approximately 150-d integrations on the Harwell IBM 360/195 computer. The results obtained predict a scientifically interesting characteristic of the dynamics of climatic change and also show that numerical experiment can be applied profitably to this important practical question.

The model uses an initial meridional distribution of solar heating, $S(\theta)$, equivalent to annually averaged and zonally averaged observed heating values. After a long integration period of about 300 d, the model apparently reaches an asymptotic 'equilibrium' dynamic state with the simulated snow-ice edge oscillating about a mean latitude of roughly 72°N. This simulation is based on the predicted model surface temperature, and includes an associated albedo distribution taken from observational data, an empirical time lag could have been built into the representation but temporal variations in the position of the edge are slow compared with the time step of integration. As such a representation would have involved further extensive computing it has therefore been omitted at this stage. The moving position of the edge is shown in Fig. 1 for a 200-d period. At the end of that period S was reduced by 0.5% and the computation continued for a further 400-d period. The calculated mean position of the ice edge over that period coincided with the result obtained previously using our statical method³. The process was repeated for successive small reductions, δS , in S . When δS approached 3% the westerly, mid-latitude, cyclonic wave type of flow became punctuated increasingly by low latitude, Hadley-cell circulations which penetrated to higher latitudes for increasing periods of time. Indications of this characteristic of climatic change have already been noted by Lamb¹. At the same time, the spatial amplitude of the oscillating edge increases sharply as δS approaches 3% (Fig. 1) although the mean position is at about the latitude predicted by statical calculations³. In the type of model used by Everson and Davies, latitude does not correspond exactly to latitude on the spherical Earth although there is a close approximation.

We deduce from these results that, although the computed movement of the zonally averaged ice edge follows roughly the results of previous statical calculations³, the dynamic model shows signs of rapidly increasing instability (reflected in the increasing amplitude of oscillation of the simulated ice edge) at each mean equilibrium position, as solar heating is reduced by up to 3%. The model is known not to reproduce the low latitude (Hadley cell) mean meridional circulations very well and several important feedback processes are omitted, there is a pressing need to study the dynamics of climatic change with more sophisticated model systems including a realistic oceanic-atmospheric link and representations of mean seasonal movements. Our initial results form, however, a step forward

from previous calculations based on statical models, and show that, although equilibrium solutions (of the Budyko type) exist with as much as 5% reduction in solar heating, their stability becomes very suspect as 3% reduction values are approached, and the atmospheric circulation changes fundamentally. This suggests that there is a danger that a further increase will trigger off a progressive movement of the snow-ice edge towards the equator. Calculations beyond this stage have not been carried out, as we feel that the premises of the model are unlikely to apply.

Detection of elastic strainfields caused by fault creep events in Iran

SLIP movements along active faults may either occur violently, and generate earthquakes, or gradually in a little understood process called fault creep¹⁻⁵. An interesting feature of fault creep is that it is frequently episodic rather than continuous and the episodes of movement propagate along the fault¹. The mathematics, but not the physics, of the process are identical to those of crystal dislocations⁶.

Although displacements across faults have been monitored carefully for some time^{4,5}, there has been almost no study of the transient strains that must be associated with the passage of each creep event. Frank⁷ has discussed the strain-time histories that can be expected theoretically during typical strike-slip creep events, and we here follow his formulation.

For a single, infinitely long, edge dislocation of slip strength, b , normal to the surface in a homogeneous semi-infinite half-space⁷

$$e_{\phi} = \frac{-b}{4\pi y} \left\{ (1-2\nu) \frac{1}{1+X^2} + (1+2\nu) \times \left[\cos 2\phi \frac{2X^2}{(1+X^2)^2} + \sin 2\phi \frac{X(1-X^2)}{(1+X^2)^2} \right] \right\} \quad (1)$$

where ν is Poisson's ratio, e_{ϕ} is the linear strain at a point x, y , $X = x/y$, and the surface trace of the fault lies along the x -axis with y chosen such that in a right-handed coordinate system z is positive upward, ϕ is the angle between strainmeter and the x -axis, and increases in an anticlockwise fashion looking down.

A screw dislocation parallel to the x axis at a depth d gives a strain of

$$e_{\phi} = -\frac{b}{4\pi y} \frac{4D}{1+D^2} \sin\phi \cos\phi \quad D > 0 \quad (2)$$

$$= 0 \quad D \leq 0$$

Where $D = d/y$. The function $-b/4\pi y$ indicates that the strain magnitude is proportional to the size of the dislocation and decays inversely with distance from the fault.

Equations (1) and (2) describe the spatial variation of strain resulting from static dislocation. If, however, the dislocation moves with a velocity which is slow compared with the shear

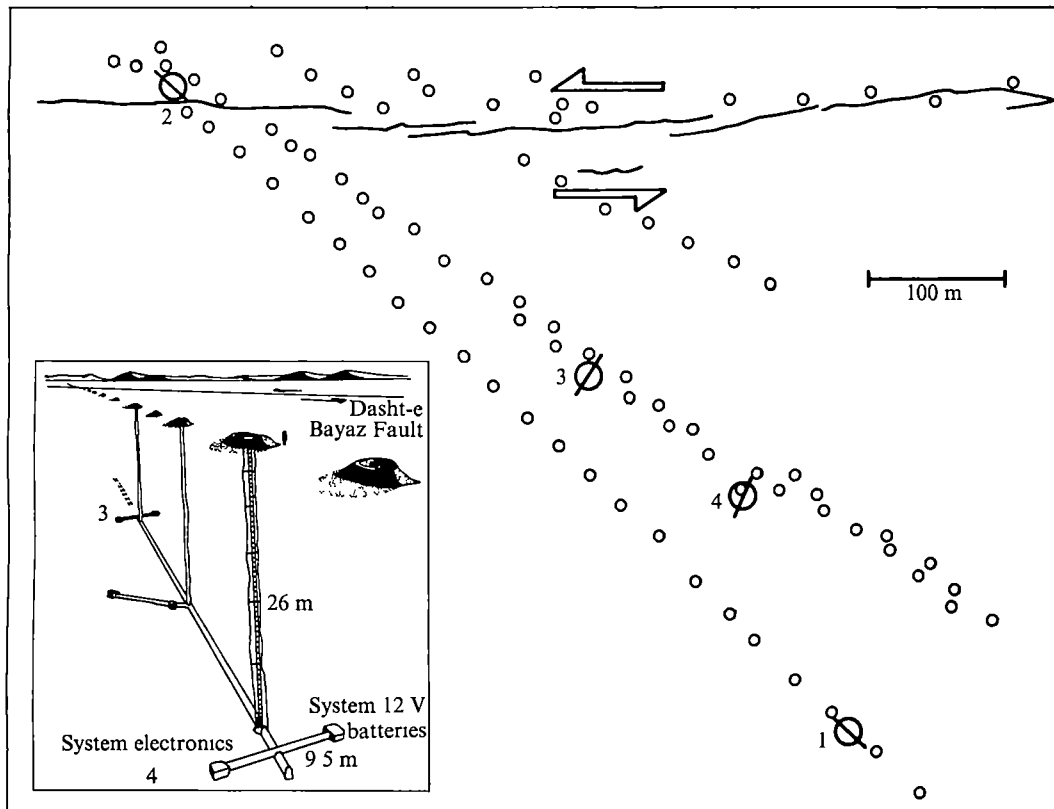

Fig. 1 The location of the strainmeters superimposed on a map of the Dasht-e-Bayaz fault break⁸. Open circles, vertical well shafts connecting qanats to the surface, 1-4, positions of strainmeters—the symbols indicate orientation. The insert shows a diagram of the qanat system containing instruments 3 and 4.

wave velocity, the strain as a function of time may be obtained by substituting

$$X = (x_0 - ut)/y$$

in equation (1) and

$$D = (d_0 - wt)/y$$

in equation (2). The parameters x_0 and d_0 refer to the position of the dislocation at time, $t = 0$, and u and w are the x and z components of the velocity. As equation (1) and (2) are not invariant with respect to a reversal in the velocity, the strain as a function of time may be used to determine the direction of propagation of a dislocation.

The instruments on which we have observed creep related strains are situated in eastern Iran near to the fault break⁸ of the 1968 Dasht-e-Bayaz earthquake. They are sited in horizontal underground irrigation tunnels called qanats (Fig. 1). These connect to the surface at regular intervals through vertical well shafts. Instruments 3 and 4 are installed in a completely separate qanat system (insert, Fig. 1) from the array comprising instruments 1 and 2. Within an array the instruments share the power supply and the recording system, but there is no electrical connection between separate arrays. These circumstances greatly reduce the possibility that a freak instrumental effect will be observed.

Column *a* of Fig. 2 shows data from the four instruments. Instruments 1 and 2 were recorded on one chart paper and 3 and 4 on a second. To record the data (Fig. 2*a*) the instruments use pressure-sensitive paper marked by a galvanometer needle that is struck every 10 s by a chopper bar. The sampling interval for instruments 1 and 2 is much longer than that for instruments 3 and 4 which gives rise to discontinuous traces (Fig. 2*a*). Tides are visible on the records and long spans of tidal data from instruments 1 and 2 and a third now defunct instrument in the same qanat have been analysed. The results (Fig. 2*a* and *b*), indicate that no significant rigidity anomalies are apparent in the region of the arrays. The very large strain magnitude observed on instrument 2 (Fig. 2*b*) excludes the possibility that a pressure effect has

been observed⁹. The temperature coefficients of the instruments are less than 10^{-7} per °C and the temperature in the instrument 2 site remains constant to within 0.1°C over periods of days. The excursion is therefore too large and too rapid to be a thermal effect.

Predicted strain signals for an edge dislocation—equation (1)—propagating eastwards ($u = 200\text{ mm s}^{-1}$, Fig. 2*c*), and westwards ($u = -200\text{ mm s}^{-1}$; Fig. 2*d*) along the fault, show clearly that an eastward, but not a westward, propagating creep event fits the data rather well. That direction of propagation is also suggested by the fact that the event first appears on instrument 2. Furthermore, the velocity of 200 mm s^{-1} both produces strain records like those observed, and accounts for the different onset times on the different instruments.

The strain records for instruments 3 and 4 for 12 h before the observation of the events described here, are significantly disturbed from the normal tidal signal for the same instruments (Fig. 3*a*). For comparison, a short section of typical tidal data for instrument 3 is shown (Fig. 3*b*). Consideration of the predicted strain record (Fig. 3*c*) for these instruments for a downward propagating (equation (2) $w = -200\text{ mm s}^{-1}$) screw dislocation suggests that some of the signal observed by instruments 3 and 4 in this 12-h period might have been produced by downward propagating creep events. These events are not, however, clearly visible on the records of instruments 1 and 2 possibly because of the high noise level or the long sampling interval.

The present network of four instruments is insufficient to permit determination of the depth and extent of the creeping surface. The event interpreted as having been caused by an edge dislocation was, however, detected to the west of instrument 2 and was still visible until it was to the east of instrument 1. It must, therefore, have propagated more than 800 m. It is of particular interest that this same event can be explained by an infinite dislocation with a slip strength, b , of less than $10\text{ }\mu\text{m}$. If the depth of the edge dislocation is limited by allowing it to generate or consume a trailing or leading screw dislocation, the size of the required slip and the form of the predicted signals are not altered significantly, unless the whole process is restricted to a few tens of metres near the surface. That is

Fig. 2 *a*, Data recorded by the strainmeters between 0900 and 1000 on April 24, 1974 (the numbers in the centre of the figure correspond to the numbers of the instruments). Traces 1 and 2 were written by an earlier and noisier design of strainmeter than were traces 3 and 4. *b*, tracings of the data shown in column *a*. The large excursion of the trace of instrument 2 (which is closest to the fault) is easily visible on the original record, though not on the reproduction in column *a*. *c, d*, Predicted strain records (*c*, for an eastward propagating edge dislocation, *d*, for a westward propagating edge dislocation). The vertical lines in columns *c* and *d* correspond to $X = 0$ in equation (1), and the arrows on the data tracings (column *b*) correspond to where the vertical lines overlay when *c* is fitted to *d*. The horizontal scales are everywhere the same. The velocity of the creep event in *b* and *c* is 200 mm s^{-1} . The vertical scales are the same and correspond to the scale bar. The amplitudes of the predicted signals have been chosen to facilitate comparison with the data. They are within $\pm 20\%$ of the amplitudes predicted by a dislocation of slip strength, $b_s = 10 \mu\text{m}$ except in the case of instrument 1 which, for clarity, has been exaggerated by a factor of 2.

Fig. 3 *a*, Records from instruments 3 and 4 for 12 h before the data displayed in Fig 2, *b*, predicted form for downward propagating ($w = -200 \text{ mm h}^{-1}$) screw dislocations, *c*, predicted form for a typical span of tidal data recorded at the same site on instrument 3.

clearly unlikely for an event which propagated at least 800 m. Models which invoke exotic departures of rigidity from an homogeneous half space are excluded by the consistency of the tidal data.

Although a creep event was previously observed on the same fault by a creepmeter 5 km from the strain array, and even though geodetically measured movement is believed to be occurring (J Brander, personal communication), no creep events were detected in association with the strain signals. That is hardly surprising in view of the fact that 10 μ m is well below the threshold level of our own and other people's creepmeters (Californian creep events are often 10³ times larger).

A further point of interest is that our predicted signals do not resemble those of typical creep events as written by creepmeters. In that respect they differ from strain records obtained at Stone Canyon¹⁰. Though it is possible that those records were produced by very localised fault creep¹⁰, or by local slumping, all of our strainmeter designs have produced records that resemble creep events on creepmeters. Our instruments have been installed at stable sites in England and we believe that these 'events' are caused by instrumental or siting problems because they usually occur randomly on closely grouped instruments.

Lineations in the Magnetic Quiet Zone of the North-west Atlantic

A MAGNETIC and seismic reflection survey in the Magnetic Quiet Zone shows that basement topography and magnetic anomalies are lineated parallel to the boundary of the quiet zone. Two narrow zones of reversed polarity are identified. The results imply that the zone boundary is an isochron separating a period of seafloor spreading in which rapid geomagnetic reversals occurred from a period in which few reversals occurred.

There have been many attempts to explain the presence of the Magnetic Quiet Zone which lies seaward of the continental shelves bordering the North Atlantic. In terms of crustal layer thickness and basement topography the quiet zone resembles normal oceanic crust. It is, however, unusual because the magnetic anomalies have a low ampli-

tude within the area. The following explanations for the attenuated nature of the anomalies have been suggested: (1) magnetisation during a time interval characterised by the absence of geomagnetic polarity reversals¹⁻³, (2) original magnetisation with very low inclinations acquired in equatorial magnetic latitudes during the Triassic⁴, (3) hydrothermal alteration resulting in reduced magnetisation⁵, and (4) intrusives rather than extrusives as the dominant component of layer 2 (ref 6). These have been reviewed by Pitman and Talwani⁷.

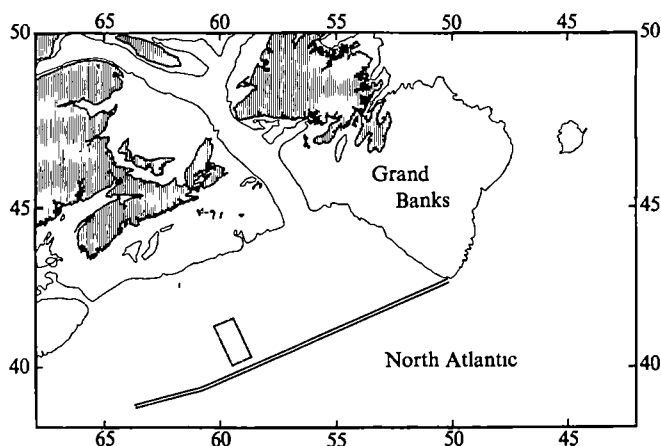

Fig. 1 Location chart showing the area of the survey (dashed lines) and the quiet zone boundary (double solid lines).

In 1972, detailed magnetic, seismic reflection and sonobuoy seismic refraction studies were carried out within an area 150 km × 70 km in the quiet zone of the North-west Atlantic (Fig 1). The purpose of the experiment was to test the hypotheses concerning the nature and origin of this area. The measurements were made from CSS Hudson at a track spacing of less than 7 km (Fig 2). Using LORAN-C in the range-range mode together with satellite navigation, the survey lines could be positioned to an accuracy of 200 m. The observed magnetic anomaly field was compared with a field calculation based on a layer of constant thickness with the observed topography of oceanic basement, so that the presence of magnetic reversals, if any, could be detected. The results provide estimates of the magnetisation of layer 2 in the quiet zone and indicate the direction of lineation of the magnetic anomalies and of topography of the top of layer 2.

Many of the experimental methods used in this study have been described previously⁸. The magnetic data were corrected for diurnal variations which are of the same amplitude, approximately 60 gamma, as the spatial variations of the magnetic anomaly field. A magnetometer manufactured by Sander Geophysics was moored in the survey area and the data from this and observations at the magnetometer station at Bedford Institute, Dartmouth, Nova Scotia, were used to make the diurnal corrections.

During the survey no unusual magnetic disturbances occurred and the r.m.s. crossover error of the corrected total magnetic field is 4.5 gamma. The anomaly field was obtained by subtracting the 1965.0 IGRF regional magnetic field⁹ plus a constant shift of 173 gamma. The latter is necessary if a mean value of zero for the anomaly field¹⁰ is desired. The magnetic data were then contoured and the resulting contour chart is shown in Fig 2.

The seismic reflection data were collected along fewer tracks than the magnetic measurements (Fig 2). Oceanic

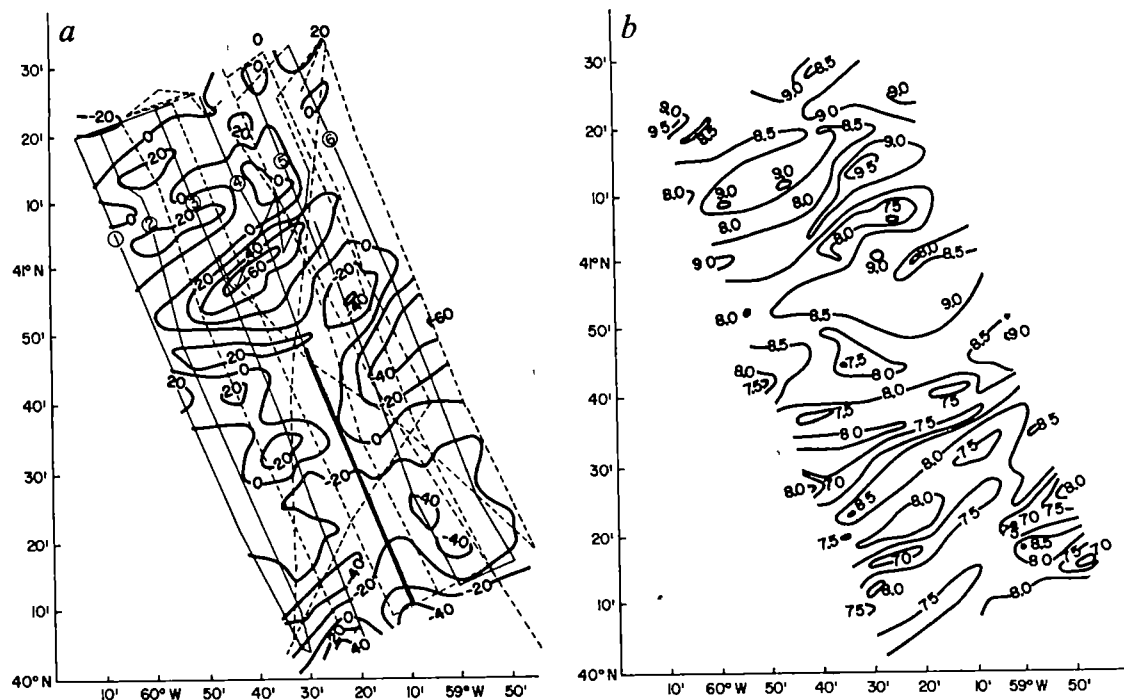

Fig. 2 Contour charts *a*, the magnetic anomalies, *b*, the basement topography, showing the tracks along which data were collected ---, Tracks along which only magnetic data were collected, —, tracks along which magnetic and seismic reflection and refraction data were obtained. The circled numbers on the solid lines are line identification numbers, used in Fig. 3. The magnetic contour values are given in gamma and the topography values are in km below sea level.

Fig. 3 The magnetic anomalies (—) and corresponding basement topography (---) along three lines. The line numbers are those indicated in Figure 2. The arrows denote positions at which there is a negative correlation between basement topography and the magnetic anomalies.

basement was invariably observed although in some instances it was difficult to determine accurately the top of this layer because of the rough nature of the reflector which caused side echoes. The depth to basement in one-way travel time was converted into distance using a mean velocity of 2.0 km s^{-1} for the sedimentary column down to horizon β and 3.0 km s^{-1} for the remainder of the section. This velocity is based on the sonobuoy results.

The contour maps of the magnetic anomalies and of the basement topography show that both are lineated approximately parallel to the quiet zone boundary (Figs 1 and 2). The magnitude of the total magnetic anomaly field varies from about 60 to -40 gamma, and wavelengths of the prominent anomalies are about 30 km, which is similar to the wavelengths of anomalies within the disturbed zone. With respect to its lineated appearance and its relief of 1 km or more, the character of oceanic basement is similar to the character of the exposed basement rocks near the crest of the mid-Atlantic ridge. This suggests a seafloor spreading origin for the quiet zone. The magnetic lineations could be a reflection of the basement trends and could also be influenced by geomagnetic reversals.

In interpreting the results, answers to three main questions concerning the quiet zone were sought.

First is there evidence that geomagnetic reversals have occurred and, if so, how frequent are they? Second, what is the magnetisation of oceanic basement? Third, was the oceanic crust formed at low geomagnetic latitudes?

To detect the presence of reversals, correlations of the magnetic anomalies with topography were made. Figure 3 shows the basement topography and magnetic anomalies along three tracks which cross the survey area. The topographic profiles show more variation than the magnetic anomalies. The attenuation of the shorter wavelength components of the magnetic anomalies is caused by the large separation (about 8 km) between the magnetic source and the level of measurements. Figure 3 indicates that the topography and the magnetic anomalies correlate well in terms of the positions of the peaks and troughs and suggests that

most of the magnetic anomalies may be caused by basement topography. But at two locations on each of the profiles there is a negative correlation. At the positions shown by the arrows in Fig 3 the basement relief is insufficient to cause the magnetic lows. This is consistently observed on all of the NW-SE tracks. So there are two strips trending parallel to the magnetic lineations where magnetic data and basement topography suggest that the basement rocks must possess reversed polarity. The good correlation between topography and magnetic anomalies elsewhere shows two significant characteristics. First, the region is predominantly underlain by oceanic basement with remanent magnetisation in the normal direction, and second the larger part of the anomalies must be caused by variations in basement topography.

A theoretical model of oceanic basement describing the topographical variations within the survey area was constructed using rectangular blocks, $1.8 \text{ km} \times 5.4 \text{ km} \times 1.8 \text{ km}$ thick. This thickness has been used by others⁴, so comparisons of results can be made easily. The blocks were aligned so that the 5.4 km length lay in the direction of the lineations and the 1.8 km length perpendicular to it. The heights of the blocks were raised or lowered to simulate the observed topography. Calculations of the magnetic field arising from this three-dimensional model were made for various values of magnetisation, magnetic inclination and strike, and for various widths of the zones of reversed polarity. With these results, an estimate of the magnetisation of the basalts can be obtained.

We computed the three dimensional magnetic anomalies using declinations and inclinations consistent with both Jurassic and Triassic palaeomagnetic pole positions for North America. A remanent magnetisation value of $1.1 \times 10^{-2} \text{ emu cm}^{-3}$ gave the best fit in the zones of normal polarity and for the sake of simplicity in the model, the same value was used in the two zones of reversed polarity shown in Fig 3. In the latter case, the high magnetisation value imposed a limit on the width of the reversed zones in the model of 1 km. A more detailed model with lower values of reversed magnetisation would undoubtedly allow the reversed zones to be wider, particularly in the southernmost zone. Simplified contour maps of the computed magnetic

anomalies for the Triassic and Jurassic models and for the observed data are presented in Fig 4. These were obtained by shading regions above 20 gamma and below -20 gamma. Although the correspondence between the observed and computed maps is not exact, the main belts of positive and negative anomalies appear in each. The Jurassic model gives the best fit to the observed anomalies in the northern part of the area where reversals do not affect the magnetic anomaly pattern. This is additional evidence to support the argument that low magnetic latitudes during the Triassic are not required to explain the magnetic anomalies in the quiet zone and further suggests that the crust is Jurassic in age. Although the models could be varied to resemble the observations more closely, the numerous geological variations which have not been included in the model together with the errors in the measurements make these refinements unrealistic.

We thank the Master, Officers and Crew of CSS Hudson for their cooperation and assistance during the survey. We are grateful to D R Locke, D E Heffler, G Bugden, and M J Keen for their support at sea and to M J Keen for reducing the sonobuoy data.

Fig 4 Simplified contour charts of the magnetic anomaly field as observed (a), calculated from the Jurassic model (b) and the Triassic model (c). Anomalies greater than 20 gamma are shown in the dotted areas and anomalies less than -20 gamma are shown by dashed areas. For the Jurassic model a magnetic inclination of 60° and declination of 0° were used. For the Triassic model the values were 20° and 20° respectively. The remanent magnetisation was $1.1 \times 10^{-2} \text{ emu cm}^{-3}$ for both models. 1 km zones of reversed polarity and the same magnetisation were used in the models at the locations indicated by arrows.

Anomalous delays of teleseismic P waves in Yellowstone National Park

TELESEISMIC P waves recorded by a short-period seismic network, comprising 12 stations, in Yellowstone National Park, show anomalous delays of 1-2 s in their travel times in the central region of the park relative to the surrounding area. To explain this phenomenon, I propose that a substantial body of low velocity material is present beneath the park, with horizontal dimensions of several tens of kilometres, it may be the magma chamber associated with the volcanism of Yellowstone (ref 1, and G P Eaton *et al*, unpublished).

This study is based on records of about 65 teleseisms, distributed in a narrow range of azimuths north, south-east, west-south-west, and north-west from Yellowstone. Distances to the events range from 25° to 90° . About 25 events are available from the south-east and north-west azimuths and 15 from the other two combined. Because of operational problems the number of events used in this study varies from station to station.

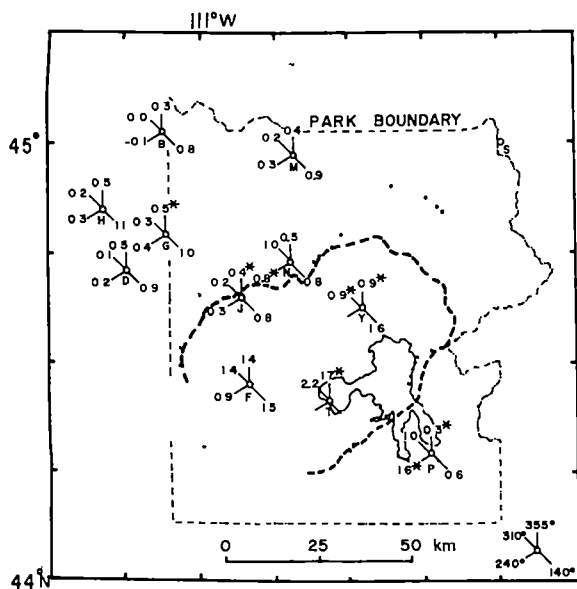

Fig. 1 Relative residuals in Yellowstone. Lettered dots, seismic stations; numbers, relative residuals with respect to station S, for events along the four azimuths (represented by the short lines); asterisks, uncertain values based on few available readings; dashed line, caldera boundary, inferred from geology and topography (ref 1, and G P Eaton, unpublished); dotted line, top of steep gravity gradient^{7,8}.

Travel-time residuals have been computed using the Seismological Tables for P by Herrin². These residuals contain a combination of station, path, and source effects and errors in earthquake location caused by the statistical nature of estimating hypocentres and origin times. Anomalous teleseismic residuals have been used in the past to study inhomogeneities in the physical properties of the Earth in the source regions of the earthquake³, along propagation paths of seismic waves⁴ and under recording stations^{5,6}. In order to isolate source and path effects from the effect of any anomalous structure in the immediate vicinity of the seismic network, one station is chosen as a reference. Residuals at the reference station are subtracted from the residuals at the other stations for each event and so-called relative residuals are obtained. Their variation across a network reflects the variation of the underlying crust and upper mantle.

The correct choice of reference station is critical, ideally it should be at a site which represents the average regional structure and which has no local anomalies. Geological evidence suggests that one of the stations well outside the Yellowstone caldera (ref 1, and G P Eaton *et al*, unpublished) is a good choice (Fig 1). To make this selection more rigorous, average residuals for events in the north-western and south-eastern azimuths have been computed at six stations at which more than 10 events are available for

each direction (Table 1). For the north-west, the residuals at the five stations outside the caldera are in the range 2.4–2.7 s but are about 1.5 s higher at station F (Fig 1), inside the caldera. For the south-eastern azimuth the residuals are 3.0–3.4 s at stations north-west of the caldera, and 4.0 s at station F. Thus, it seems that waves from the south-east, which pass under the Yellowstone caldera at some depth, are delayed relative to waves travelling from the north-west. Only at station S (Fig 1) is the average residual for both azimuths comparable to the residuals for waves that do not travel under the caldera. It therefore seems reasonable to assume that the average residuals at station S are representative of regional structure and independent of sub-caldera structures, so station S is used as the reference.

Relative residuals with respect to station S at four typical stations, for events in the north-westerly and south-easterly directions, plotted as a function of distance from the event, show clearly the azimuthally dependent travel-time delays in Yellowstone (Fig 2). At station F the relative residuals remain more or less constant at around 1.5 s for both azimuths, in the available distance range of 25°–85°, at stations G, M and B, on the other hand, the south-eastern residuals are consistently higher than the north-western values by about 0.8 s, suggesting the presence of a low velocity body under the caldera. There is some inevitable scatter in the plots, with a standard deviation of about 0.2 s around the average values. Of these stations, only station B shows a significant distance effect: the residuals around 80° are smaller than those at shorter distances by about 0.5 s. The angle of emergence of the rays changes from

Fig 2 Variation of relative residuals as a function of distance at stations F, G, M and B. Dots and crosses, events in the south-eastern and north-western azimuths, respectively; solid and dashed lines, average of the data for those directions.

Table 1 Average residuals R , for events in the south-eastern and north-western azimuths

Station	South-east			North-west		
	No of events	R (s)	Standard deviation	No of events	R (s)	Standard deviation
M	23	3.3	0.6	17	2.7	0.5
F	19	4.0	0.5	19	3.9	0.4
G	22	3.4	0.6	23	2.7	0.5
D	14	3.0	0.6	17	2.7	0.5
B	18	3.2	0.7	23	2.4	0.5
S	22	2.3	0.6	23	2.5	0.6

Fig 3 North-westerly trending vertical cross section of the low velocity body that possibly explains the travel time delay pattern. The boundary of the body is shown by a heavy solid line where well constrained by the data, by a dotted line where only poorly constrained, and by question marks where the boundary cannot be determined. Arrows, schematic ray paths for events in the north-western and south-eastern azimuths. Width of the dark shaded band (Moho) indicates uncertainty in crustal thickness¹³.

30° to 17° to the vertical as distance changes from 25° to 80°. The distance effect could occur if a low velocity body, of a particular shape and position provides equal path lengths for rays that reach stations F, G and M at various angles, while at station B, the steeper rays sample a deeper and probably narrower part of the body.

Consideration of the average relative residuals at stations F, Y and T within the caldera (Fig 1), shows that station F records large delays for all azimuths. Although the quality and quantity of data at stations Y and T are poor, the good data and a careful examination of all the available low quality seismograms show that stations Y and T are similar to station F, with high delays for all azimuths. Station N, at the edge of the caldera, almost fits into this pattern, except that it records a slightly lower northerly delay. As a first-order interpretation of the delay pattern at stations F, N, Y and T, it can be postulated a body with lower compressional wave velocity than the surrounding rocks exists under the central region of Yellowstone National Park. The top of the body must be close to the surface in the middle of the park, as shown by the large delays for all azimuths. At the north-western group of stations, M, B, G, H and D, which is outside the caldera, the relative residuals are about 1 s for events from the south-east and much lower for the other azimuths. The low velocity material must, therefore, extend to a depth such that the rays from the south-east reaching the north-western group of stations at angles of 17°–30° to the vertical traverse through that material.

It is also possible roughly to define the horizontal extent of the low velocity body. There is a sharp difference in the azimuthal pattern of relative residuals between stations F and J (Fig 2). The delays are high for all azimuths at station F, whereas at station J, the south-easterly delay is much higher than for the other azimuths, indicating the existence of a boundary to the body to the south-east at some depth from station J. The northerly delays decrease from the high values at stations F, T and Y to about 0.5 s

at stations J and N, indicating shorter paths through the body for rays reaching the latter stations, that indicates a boundary not far north of the caldera boundary. South-easterly delays seem to decrease between stations Y and P, placing a limit on the south-easterly extent of the body. The available data are not inconsistent with the *ad hoc* hypothesis that the horizontal boundary of the top of the body is near the caldera rim.

The region of the Yellowstone caldera has a negative Bouguer gravity anomaly with sharp gradients close to the geologically determined caldera boundary^{7,8} (Fig 1). The gravity low is believed to be produced by the partial presence of low density material such as rhyolite flows, magma and caldera fill. That explains only a small fraction of any observed teleseismic delays, however. A 10 km thickness of material with a conducting seismic velocity 10% lower than the surrounding rock would introduce a delay of only 0.2 s. Only teleseismic evidence, in particular the large delays at the north-western group of stations, shows that seismic rays are delayed at some depth under the caldera. High frequency seismic waves from local earthquakes in the region are severely attenuated as they cross the Yellowstone caldera (G. P. Eaton *et al.*, unpublished). Yellowstone has a history of volcanism extending from about 2 Myr ago to as recently as 0.07 Myr ago. A low velocity body comprising rhyolitic magma a few kilometres thick overlying an immense volume of basaltic magma and thermally disturbed crustal and mantle rocks, could be responsible for the gravity anomaly, the seismic wave attenuation, and the teleseismic delays, it is also consistent with the geological evidence (ref 1, and G. P. Eaton, unpublished).

A tentative model for the low velocity body is suggested. If the compressional velocity in this body is assumed to be 10% lower than in the surrounding granite, the pattern of delays observed along a section from stations P to H are explicable (Fig 3). This is a very conservative model based on an angle of emergence at the surface of 25°, for events at an average distance of about 50° from Yellowstone.

It has been proposed that Yellowstone lies above a deep mantle 'plume' of hot magma, perhaps 100–200 km in diameter, rising from the lower mantle^{10,11}. Anomalous seismic velocities, recorded using teleseismic methods, have been reported near the core-mantle boundary under Hawaii, another likely 'plume' region^{4,12,13}. It is of interest that even at the most north-western station, B, large south-easterly delays still persist, indicating that the anomalous body is perhaps deeper than the maximum depth seen by the network. Preliminary results, obtained using a north-westerly profile of portable stations extending about 200 km from the boundary of Yellowstone Park, show that the anomalous body may extend several hundred kilometres deep into the upper mantle¹⁴.

THE Kuroko strata-bound sulphide deposits in Japan, which are mined for lead, zinc, copper, silver and gold, are apparently related to Middle Miocene submarine acidic volcanism of the Green Tuff region¹⁻⁵ (Fig. 1). Most of the Kuroko deposits occur in the upper part of the Nishikurosawa stage (≈ 14 Myr) of the Middle Miocene and, on geological grounds, are considered to have been formed in a short time⁶. Here I describe an attempt to determine the length of time involved from the magnetic polarity of associated rocks.

Most of the results have been obtained from red ferruginous chert, which commonly overlies the Koroko ore in beds 1–10 m thick. Chert deposition seems to have been the last stage in the Kuroko mineralisation process⁷. The chert consists of quartz (diameter 10–600 μm) and very fine grained haematite, with minor pyrite and barite. The average grain sizes^{8,9} of the haematite determined from Furutobe and Kosaka mines (Fig. 1) are 150 \AA and 95 \AA respectively. The initial grain size between the single-domain and superparamagnetic range is usually assumed to be about 290 \AA (ref. 10), so much of the haematite is probably superparamagnetic. Nevertheless a substantial number of larger grains must be present because the remanent magnetisation is very stable. The remanent intensity drops only a few per cent, and the directions remain unchanged, after demagnetisation in alternating fields of 600 oersted. Also hysteresis loops for fields up to 19,000 oersted show essentially a straight-line increase, with no tendency to saturation. The magnetisation is probably a chemical remanent magnetisation^{11,12}.

Fig. 1 Distribution of Kuroko deposits *a*, Zone of Miocene volcanism, *b*, zone of Neogene folding

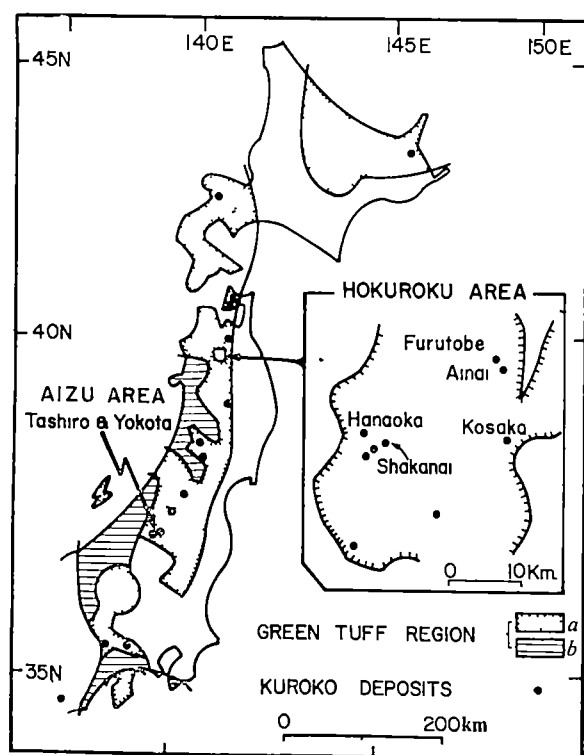

Fig. 2 Geological columns of the Furutoba and Kosaka mining districts in the Hokuroku area, and of the Tashiro and Yokota mining districts in the Aizu area. 1, Tuff, 2, tuff breccia, 3, volcanic breccia, 4, mudstone, 5, rhyolite, 6, basalt, 7, Kuroko ore body, 8, ferruginous chert. L, Lower ore bodies, U, Upper ore bodies. For explanation of M₁, M₂ and B see text. The ages are from Ikebe *et al.*²¹

(Fig. 2) The lower half of M_2 has microfossils of the Nishikurosawa stage and its upper half has microfossils of the On-nagawa stage^{3,13}. At Furutobe mine in the Hokuroku area the sequence is Kuroko ore, ferruginous chert, mudstone M_2 and basalt B_1 (ref. 14) (Fig. 3). The chert has reversed magnetisation (10 samples, mean intensity 500 μ gauss), the mudstone has normal magnetisation (three samples, intensity 50 μ gauss, remanent coercivity 200 oersted) and the basalt has normal magnetisation (three samples, intensity 2,000 μ gauss, remanent coercivity 150 oersted). At Aina mine¹⁵ the ferruginous chert has reversed magnetisation (five samples, intensity 50 μ gauss). The chert at Hanaoka mine has both normal and reversed magnetisation (two normal samples, six reversed samples, intensity 30 μ gauss) and at Shakanai mine⁵ the ferruginous chert that occurs in the lower part of the ore body has reversed magnetisation (three samples, intensity 200 μ gauss). The ferruginous chert at Kosaka mine occurs in the mudstone M_2 (ref. 16) (Fig. 3). Samples taken from directly above, and at some distance from, Kuroko ore have normal magnetisation (nine samples, intensity 100–800 μ gauss).

The Tashiro and Yokota mines in the Aizu area have similar geological sequences¹⁷. There are two mudstone layers, the lower contains microfossils of the Nishikurosawa stage, and the upper microfossils of the On-nagawa stage, just as in the Hokuroku area (Fig. 2). The Aizu area is exceptional in that there are two different ore horizons—there is an upper ore body at the same horizon as in the Hokuroku area and a lower one (Fig. 2). Two layers of chert directly overlay both upper and lower ore bodies. Ferruginous chert associated with the upper ore bodies has reversed magnetisation (six samples, intensity 50 μ gauss) but that associated with the lower ore bodies has normal magnetisation (six samples, 50 μ gauss).

The polarity results are plotted on the basis of the known stratigraphy in Fig. 3. All the Kuroko deposits, except the lower ore bodies in the Aizu area, seem to have been formed in one reversed polarity interval. Soon after the formation of the Kuroko deposits the geomagnetic field changed from reversed to normal, and lower ore bodies in the Aizu area were apparently formed in the preceding normal interval. The upper part of the Nishikurosawa stage seems, however, to have been laid down in an interval of reversed polarity. This is consistent with evidence of the short reversal interval in the upper part of the Nishikurosawa stage from measurements on volcanic and sedimentary rocks in the Green Tuff region^{18,19}

If the magnetic stratigraphy of the Middle Miocene were perfectly known, the exact time interval during which the

Kuroko deposits formed could be determined from the evidence summarised in Fig 3. Of course this is not yet possible, but an estimate can be made from the time scale of Heirtzler *et al.*²⁰. On this scale five reversed intervals occur between 12 and 15 Myr. As the Kuroko deposits, apart from a few exceptional deposits which occur in a different horizon, were formed in a single polarity interval within that time span, it is reasonable to conclude that they were laid down in less than 0.2 Myr. These results support the supposition that the Kuroko ores are of syngenetic origin¹⁻⁷. They also indicate that the ores were deposited essentially contemporaneously in both the Aizu and Hokuroku areas, more than 300 km apart.

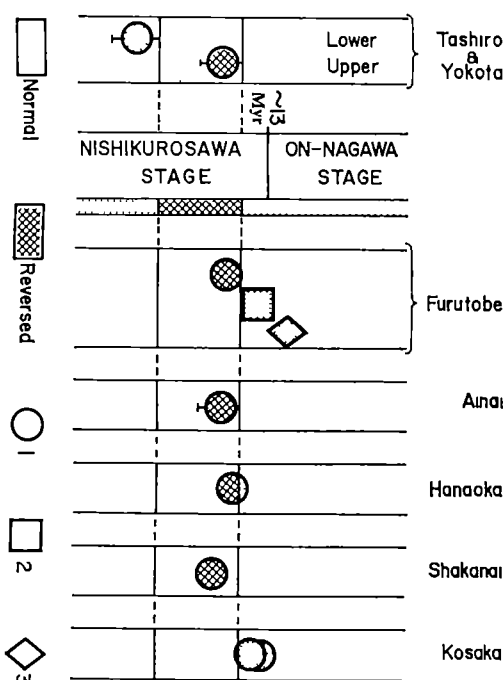

Fig. 3 Polarities plotted on the basis of the known stratigraphic sequence 1, Ferruginous chert, 2, mudstone, 3, basalt. Upper and Lower are the upper and lower ore bodies in the Aizu area.

I thank Dr E. Irving of the Department of Energy, Mines and Resources, Ottawa, Dr Takeo Sato of Geological Survey of Japan, and mining geologists of Dowa Mining Co., Mitsubishi Metal Mining Co., Nippon Mining Co. and Nishi-Aizu Kaihatsu Co. for help.

Deglaciation of the Labrador continental shelf

It has long been inferred from studies of glacial features on land that the North American Quaternary glaciers extended far out on the Atlantic continental shelf^{1,2}. Only within the last ten years, however, have offshore studies^{3,4} on the Scotian Shelf convincingly demonstrated the presence of a system of submarine moraines. This study, which used 1,100 km of deep-towed 3.5 kHz sparker profiles, 1,200 km of side-scan sonar records, 2,000 km of echo sounding profiles and 165 bottom sediment samples collected during cruises of CSS Dawson and CFAV Sackville has identified moraines and other relict glacial land forms on the outer Labrador Shelf.

More than 20% of the Hamilton Bank area is topographically rough (bottom type I, Fig. 1) and has a local relief of 10-30 m (Fig. 2c, d). Side-scan sonar representations of this irregular surface are characterised by mottles, bathymetric charts⁵ show numerous roughly circular, closed depressions deeper than 10 m. Adjacent areas with a more gently undulating surface without closed bathymetric depressions are recognised as a separate morphological region (bottom type II, Fig. 1). A zone of extremely smooth, flat topography (bottom type III, Fig. 1) is distinguished as still another morphological unit. Side-scan records reveal that the uniform bottom in this area is relieved only by occasional iceberg plow marks. Sparker profiles reveal a hard bottom with acoustic penetration generally <10 m, similar to the rest of the bank.

Moraines of the Hamilton Bank region (Fig. 2a, b) seem identical in dimensions and in transverse section to those of the Scotian Shelf³ and to terrestrial end moraines in southern New England⁶. Moraines are traceable along the foot of the landward facing bank margin and across the surface of the bank (Fig. 1).

The sharpness of existing relict features implies that they have been affected little by post-glacial sedimentary and erosional processes. Surface sediments, however, are not relict and seem to have reached a partial equilibrium with present oceanographic conditions. In general, the sediments are similar to those reported from elsewhere in glaciated offshore eastern Canada and New England^{3,6-10}.

Identification of probable end moraines and the ubiquitous distribution of coarse gravel and cobbles, as well as the excellent state of preservation of glacial landforms, strongly imply that the entire continental shelf was glaciated by the Laurentide ice sheet during the Wisconsinan. Coarse sediments, which appear in places on the continental slope to at least a depth of 400 m, may have been deposited beneath a floating ice shelf¹¹. Sills covered by a coarse gravel and boulder lag at the seaward end of Cartwright and Hawke Channels are interpreted to be mounds of detritus deposited beneath the ice shelf at a point just seaward of the grounding line¹². Although Hamilton Bank was completely ice covered, the greatest ice discharge seems to have been through these transverse channels. There is on average about 100-150 m of glacial drift in the channels compared with 50 m on the bank^{13,14}.

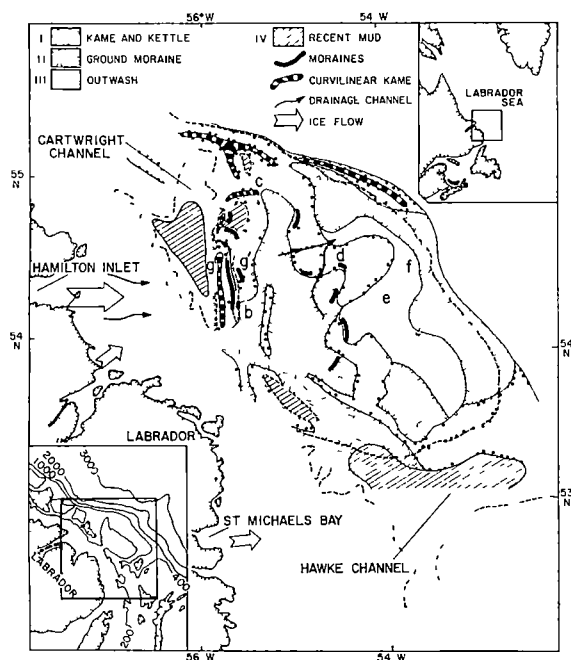

Fig 1 Physiographic-surficial geology map of the Hamilton Bank area. The dashed line is the 300 m contour and all areas completely enclosed by this contour are basins. Letters refer to sections in Fig 2. Flow directions of continental ice are inferred from the Glacial Map of Canada²⁰.

Once deglaciation had begun, ice on the bank must have retreated by calving until an equilibrium between ice thickness and water depth was reached^{15,16}. Bottom type I (Fig 1) seems to have formed as the remaining portion of the grounded ice sheet melted *in situ*. Morphologically, this bottom closely resembles terrestrial kame and kettle topography. This, together with the stratification detected in cores¹⁰, leads me to term these features 'subaqueous' kames and kettles. Kames probably formed beneath the stranded, stagnant ice sheet (Fig 3) as cavities caused by uneven bottom melting filled with an accumulation of semi-stratified detritus dropped from the undersurface of the ice¹¹. Subaqueous kettle holes seem to be the result of the disintegration and flotation of grounded masses of ice that had been surrounded by drift.

Melt water flow and perhaps tidal currents beneath the grounded ice formed a system of drainage channels (Fig 1) and provided a route for the transport of bed load and suspended sediment by hyperpycnal flow to deglaciated portions of the shelf. The resulting deposits, winnowed and spread southward over previously deposited drift by the prevailing Labrador Current, may have created bottom type III (Fig 1). This area is as flat as (Fig 2e, f), and seems to be analogous to, terrestrial outwash plains such as those of New England on Martha's Vineyard and Long Island².

Curvilinear kame features (Fig 1) are recognised by their relatively smooth flat tops and weak stratification with some evidence of ice contact disruption of bedding near the margins (Fig 2g-g'). They are thought to have formed where debris laden glacial runoff was impounded in temporary ice lakes or bays situated between ice tongues. The transverse channel sills and a terrace along the seaward edge of the bank (Fig 1), although generated beneath a floating ice shelf, are included in this category because it seems probable that they consist of semi-stratified drift. In contrast, end moraines on the bank are believed to have formed along a grounded ice sheet margin. Their irregular topography is seen as indicative of rapid deposition with little chance for the development of stratification. The

curvilinear trend of end moraines across the central bank (Fig 1) was probably formed during a readvance of the bank ice cover following the initiation of general deglaciation. The gently undulating surface (bottom type II, Fig 1) which may be ground moraine, marks the area overridden by this readvance.

Preserved ground moraine and a lack of subaqueous kames and kettles landward of the end moraine complex indicate that once the readvance had ceased, the ice sheet broke up and dispersed with little melting in place. For the remainder of the deglaciation period, active ice tongues and stagnant ice lobes were confined to the transverse channels where they gradually decreased in size leaving a complex pattern of marginal and end moraines, kame terraces and kame and kettle topography.

Fig 2 Traced profiles of glacial and pro-glacial features on Hamilton Bank. a, b, moraines; c, d, kame and kettle topography; e, f, outwash plain; g-g', large linear kame, with weak stratification evident. Types of profiles include echo sounding (a), deep-towed sparker (b, c, d, e, f) and 5 inch³ air gun interpretation (g-g', ref. 29).

It is significant that Wisconsinan glacial ice was grounded on Hamilton Bank and in the transverse channels, because it has been established that at water depths greater than a critical value, buoyancy and the strength of glacial ice permit the survival of only those ice sheets that have sufficient lateral resistance to spreading¹⁵⁻¹⁸. This resistance may be supplied by confinement between anchoring headlines or by a strong coupling to the substrate as in a cold (frozen) based ice sheet¹⁵. In West Antarctica the critical depth is about 170 m (ref. 17). Allowing for a Wisconsin glacioeustatic sea level lowering of 100 m (ref. 19), 80 m or more of glacioisostatic depression on the bank, which today averages about 190 m below sea level, would have produced depths greater than 170 m. Because the levels of raised beaches and marine deposits along the south-eastern Labrador coast²⁰ make at least that amount of glacioisostatic depression extremely likely, an initially cold based ice sheet on the bank is strongly implied. Thus, deglaciation of the Labrador Shelf in the Hamilton Bank area may have been directly caused by a decreased resistance to spreading by decoupling the ice from the substrate. This occurred

Fig. 3 Schematic representation of hummocky stagnant ice sheet on Hamilton Bank. Stippling represents semi-stratified drift and channel deposits. Black shading is outwash transported by hyperpycnal outflow (wavy arrow) from subglacial channels. This may have been augmented by tidal currents. Debris freed from the ice sheet by bottom melting is shown accumulating on ice-free portions of the bottom forming subaqueous kame deposits. Subaqueous kettles are produced by the flotation and removal of grounded ice masses.

probably during a period of rising summer air temperatures which warmed the ice sheet and precipitated a change from cold to wet-based glacial conditions. In Antarctica grounded ice sheets and ice shelves are thought to be unstable where the average air temperature for the warmest month is above 0°C (ref. 16).

Faunal evidence indicates a warming of ocean water in the eastern Arctic region beginning before 8,000 yr BP (refs 21, 22). The Cockburn-Cockrane readvance of closely similar age has been interpreted²⁴⁻²⁵ to be the result of a glacial surge to a new equilibrium profile in response to rapid deglaciation of a part of Hudson Bay²³. It is therefore tempting to speculate that the retreat of ice from the seaward edge of Hamilton Bank occurred at about the same time as the opening of Hudson Bay and that both areas were deglaciated in response to a general warming of the ice sheet. The ensuing readvance on Hamilton Bank is seen as an adjustment to a new equilibrium profile and as a corollary to the Cockburn-Cockrane event²³.

A radiometric deglacial chronology for south-eastern Labrador has not yet been established. Deglaciation dates of 16,000–14,000 yr BP have been inferred for the Labrador Shelf²³, but published²⁶ and unpublished ¹⁴C dates from the Hamlet Inlet area are consistently younger than 8,700 yr BP. These dates and the probable triggering effect of the climatic warming imply that deglaciation of the Labrador Shelf may have been in progress as late as 9,000 yr BP (refs 26–28).

Eastcan Exploration Ltd, Calgary, supplied the V-fin used in this study. Information on unpublished ¹⁴C dates was supplied by R. J. Fulton of the Geological Survey of Canada. Dr W. J. M. van der Linden proposed this project and collected most of the data.

Survey of three megalithic sites in Argyllshire

THREE sites showing simple alignments of standing stones in Argyllshire were tested for possible astronomical significance by members of the Cambridge University Astronomical Society during August and September 1973. The sites were surveyed in detail with a portable (20" circles) vernier theodolite, on which comprehensive tests were made before and after the expedition to determine adjustment errors, brief checks were made on site. Absolute azimuths were determined accurately by making timed observations of the Sun using MSF Rugby as the standard time signal. The error in azimuth was normally $\pm 10''$ and in altitude $\pm 20''$, although the latter value had to be modified to take account of uncertainties in atmospheric refraction. There is extensive information available on the Ballochroy site¹⁻³, and brief details of the sites at Loch Seil⁴⁻⁶ and Loch Nell^{4,6} have been published.

As so much importance has been attached to the site at Ballochroy we surveyed it hoping to produce more accurate profile measurements. The site contains three menhirs aligned with the Island of Cara to the south-west, with the flattened faces of the central stone indicating approximately the direction of Corra Bheinn on Jura to the north-west. A kist lies 40 m south-west of the three menhirs, and is

Fig. 1 Midwinter sunset over Cara Island (NR638438) shown for, a, 1600 BC (obliquity of ecliptic, $\epsilon = 23^{\circ}53'09''$) and, b, 1800 BC ($\epsilon = 23^{\circ}54'28''$) as seen from the menhirs or the kist at Ballochroy. Profile of Cara shown below. Errors in altitude of $\pm 0.7'$ are estimated from a temperature variation of $\pm 3^{\circ}\text{C}$ around 5°C at sunset, and from a measurement error of $\pm 0.35'$.

Table 1 Observed lines at Loch Seil (*a, b, c*) and Strontouiller (*d, e, f*)

Line	Az*	h*	δ^*	Notes
<i>a</i>			-21°	Alignment—no obvious foresight

<i>c</i>			+6°	Alignment—no obvious foresight
<i>d</i>	305.3°	+3.6°	+20.9°	Cross sight line, notch
<i>e</i>	307.5°	+3.0°	+21.5°	Cross sight line, pit
<i>f</i>			-21.8°	Ref 3 (not surveyed—trees)

*Azimuth (Az), altitude (h) and declination (δ) are given for well defined lines

approximately collinear with them. Weather conditions during our survey were variable, especially over the Paps of Jura, but repeated observations over a 3-h period showed refraction to be constant. For calculating the track of the setting Sun we used astronomical refraction tables^{7,8}. We followed Thom's method⁹ to allow for changes in our measured altitudes caused by local terrestrial refraction.

An observer at the site looking towards Cara in 1580 (± 100) BC would have seen the top limb of the midwinter Sun set just clear of the island (Fig 1). An observer looking towards the north-west from the central stone would have seen the midsummer Sun's upper limb clip the top of Corra Bheinn in 1640 (± 70) BC, standing near the kist in 1600 (± 70) BC he would have seen the Sun twinkle down the slope of Corra Bheinn (Fig 2). Thom postulated^{1,3} that the site was constructed to observe these phenomena. The accuracy of our survey and the similarity between the dates quoted lends support to this view.

Fig 2 Midsummer sunset behind Corra Bheinn (NR526755) at 1600 BC ($\epsilon = 23^\circ 53' 09''$) as seen from centre menhir (---) and kist (—). Errors in profile altitudes of $\pm 0.5'$ are estimated from a temperature variation of $\pm 3^\circ\text{C}$ around 13°C at sunset, and from a measurement error of $\pm 0.35'$.

The principal stones on the site near Loch Seil, Kilmiver are three menhirs 2.5 m high, the centre stone is somewhat tilted. The stump of another menhir, apparently broken since Thom's survey³, was found 40 m away. The possible stump of another menhir, accurately in line with the other outlier and the centre menhir of the group of three, was found 180 m away. Skyline profiles, all of which were less than 3 km distant, were surveyed in both directions along the line of the three principal stones (Table 1, *a* and *b*), and in the direction indicated by the outliers (Table 1, *c*). Declinations for these lines are given in Table 1, we agree with Thom's declinations⁴ but find no well indicated foresight for his solar line and do not think his Capella line significant.

The site at Loch Nell, near Oban, is near a farm the name of which—Strontouiller—is Gaelic for 'point of light'. It has a menhir 4 m high and a possible 1 m menhir 50 m to the south-east with a ring cairn 3 m in diameter between them. The small menhir has a gate hung from it, but because of its size and shape it seems unlikely that it

was erected for this purpose. About 300 m to the north-west of the large menhir is a circle (15 m in diameter) of boulders, which is possibly all that remains of a despoiled cairn. An outcrop of rock, on which there seems to be a cairn 20 m in diameter, lies between the circle and the menhirs and restricts the view of the menhirs from the centre of the circle. The two menhirs are aligned with a small hill 600 m away.

The top of the larger menhir has been flattened (an unusual feature) and slopes at the same angle as the hill. The cross-sight lines indicated by opposite edges of the menhirs point accurately at two prominent gaps on the hillside (Fig 3). One is a pit 4.5 m wide which has earthworks at its sides. The other is an apparently artificial, 1 m wide, V-shaped notch cut into the rock. The notch and pit

Fig 3 Left, skyline profile to the west at Strontouiller seen from behind the 1 m menhir, 4 m menhir indicates notch *d*. Right, cross bearings indicate notches *d* and *e* with setting declinations $20^\circ 56' 1''$ and $21^\circ 28' 2''$. Ring cairn shown dotted.

lines (Table 1, *d* and *e*) indicate accurately a limb of the setting Sun at declinations $20^\circ 56' 1''$ and $21^\circ 28' 2''$ respectively. We think that these declinations have no particular astronomical significance. Thom⁴ gives another (calendar) line at this site (Table 1, *f*), indicated by the large menhir from the circle. The Ordnance Survey marks the farm on the hill as 'Duneil' (dun is Gaelic for fort), which suggests that the earthworks are of recent rather than megalithic origin. Also, there are further earthworks on the southern slope and behind the hill. Thus, we conclude that such convincing alignments may have occurred only by chance, this view, however, requires confirmation by independent archaeological work. (Other profiles indicated by the flat sides of the large menhir were surveyed but these too, in our opinion, have no astronomical significance.)

The survey of Ballochroy shows that the site could have been used to observe the midwinter and midsummer setting Sun in 1600 BC. The alignments at the other two sites are not, in our opinion, consistent with possible astronomical usage, despite the existence at the Loch Nell site of seemingly convincing artificial foresights.

We thank Mr D. S. Green, Department of Engineering, Cambridge University, for the loan of a theodolite, and Mr S. N. Henbest and Miss H. A. Couper for their help at Loch Seil and Loch Nell.

Mineralogical alteration of Chinese tomb jades

ADMIRERS of ancient Chinese jades have frequently noted the curious white, chalky areas which invade the otherwise firm polished surfaces of many artefacts. This phenomenon, variously described as "alteration", "calcification", "calcination", or simply "decay", seems to be restricted to ancient (Shang to Han Dynasty, 1766 BC to 220 AD) 'tomb jades', artefacts explicitly or implicitly connected with burials¹. We have examined artefacts exhibiting this alteration using X-ray powder diffraction and scanning electron microscopy. We postulate that the alteration consists of a selective dissolution (leaching) along grain boundaries by ammoniacal solutions of high pH produced during decay of the corpses with which the jades were buried. Analyses by

Fig. 1 Chou Dynasty tiger (?) (Buffalo Museum of Science No. J-294) of pale green nephrite, illustrating typical partial alteration. Overall length 5.3 cm.

Fig. 2 Scanning electron photomicrographs of surface of nephrite artefact. *a*, Unaltered surface (width of field 100 μ m); *b*, altered surface (width of field 100 μ m).

X-ray powder diffraction of a number of partially altered jades showed them all to be nephrite (a fine grained, compact variety of the tremolite-actinolite series of amphiboles). This mineralogy is consistent with the antiquity of the artefacts, since the other jade mineral, jadeite (a pyroxene), was not introduced into China until the eighteenth century AD^{1,2}. Interestingly, the diffraction patterns of altered and unaltered regions are identical (also noted by West³), indicating that the alteration does not involve any change in mineral composition. This invalidates the terms calcification and calcination which, respectively, imply chemical replacement and thermal decomposition. It is likely that these terms were coined with reference to the white, ivory-like 'chicken-bone' jades which are produced by heating nephrite: calcification because of the bone-like appearance, and calcination referring to the method of production. The original nephrite in the 'chicken-bone' jades has, however, decomposed with loss of structural water into a diopside-enstatite-silica assemblage which is easily distinguished in diffraction patterns.

Altered surfaces are characteristically white or buff-coloured; they are softer and less reflective than adjacent unaltered areas. Occasionally artefacts will be completely altered, usually with badly eroded surfaces, although more commonly, only certain areas are altered (Fig. 1), with only shallow penetration, preserving the details of intricately carved surfaces. The boundaries between altered and unaltered regions are typically relatively sharp. A curious patterned alteration occurs on some Archaic ceremonial knife blades, described as "fabric-marked", in the form of small orientated blebs, reminiscent of the pattern of a coarsely woven cloth.

The change in colour, hardness, and reflectivity of the altered surface, coupled with the lack of change in mineralogy, suggests chemical etching as a likely cause of the alteration. We therefore examined the surface microstructure of altered and unaltered areas of a Chou Dynasty (1122 to 206 BC) artefact (Fig. 1) with a scanning electron microscope. The results show that the unaltered surface is compact and smooth, even at high magnification (Fig. 2*a*), whereas the altered surface consists of an open, felted network of acicular tremolite crystals (Fig. 2*b*). (Comparative X-ray emission spectroscopy of altered and unaltered surfaces reveals no significant difference in chemical composition.)

This suggests that the mechanism of alteration is a selective congruent dissolution (leaching) along grain boundaries. It has previously been suggested that the alteration may result from the action of soil acids and moisture^{1,2}, and may be accelerated by decomposition products of the bodies in the tombs¹. Experimental studies³ indicate that the solubility of tremolite is at a minimum in solutions of pH from 3 to

8, the range of most natural soil waters. Furthermore, solubility studies of tremolite and other silicate minerals show that dissolution in acidic waters is incongruent, leaving a solid residue of silica, and is extremely slow⁴. Dissolution in basic ($pH \geq 9$) waters, however, is congruent and relatively rapid.

There seems to be no correlation between the degree of alteration of nephrite artefacts and their archaeological age or their length of burial. Thus chemical 'weathering', resulting from the action of soil moisture, does not seem to be a viable explanation for the observed alteration. We propose that the alteration consists of congruent dissolution of nephrite, preferentially along grain boundaries, that the alteration takes place in relatively short times, perhaps months, and that it is produced by the action of basic (high pH) rather than acidic solutions. Alteration of select areas of nephrite in sharp contact with unaltered areas may result from differences in the fabric (microstructure) of domains in the polycrystalline material⁵.

Fig. 3 Scanning electron photomicrographs of *a*, artificially altered nephrite surface (width of field 10 μm); and *b*, altered surface of nephrite artefact (width of field 33 μm).

Conditions suitable for such alteration could be produced and maintained for adequate periods in the tomb environment. Degradation of proteins during liquification of body tissues accompanied by bacterial decay could produce ammoniacal solutions of high pH . In a sealed coffin, such solutions would alter nephrite artefacts buried with the body. The degree of alteration would thus be a function of the degree and duration of contact between the artefact and solution as well as the microfabric of the nephrite. Fabric-marked blades could result from 'wicking' of basic solutions to the blade surface by cloth funerary wrappings.

To test this hypothesis we immersed polished nephrite slabs in solutions containing ammonium hydroxide for several weeks at room temperature. The resulting alteration (Fig. 3*a*) is essentially identical to, although less severe than, that of the artefact examined (Fig. 3*b*). The partial alteration of this nephrite, which was totally immersed in the solution, illustrates the importance of the microfabric to the rate of alteration. Domains of randomly oriented tremolite needles are more susceptible to dissolution than those possessing a high degree of orientation. Alteration also occurred more rapidly along fractures and unpolished surfaces, presumably as a result of disruption of oriented microfabrics at fracture surfaces.

The ancient Chinese buried jade with their dead to prevent decomposition of the body—during the Han Dynasty pieces of jade were placed in each of the body orifices to ward off decay. It is ironic that the corpses caused the decay of the jade.

We thank Virginia Cummings and Clifford Awdal of the Buffalo (New York) Museum of Science for loan of artefacts, and Robert White (University of Pennsylvania) for assistance with the scanning electron microscope.

Adsorption of divalent phosphate on hydrous aluminium oxide

THE adsorption of phosphate on aluminium and iron hydrous oxides is of practical importance in soils because of its influence on the availability of this nutrient to plants. One aspect of phosphate adsorption is the release of hydroxyl ions into the solution. This paper reports a quantitative relationship between divalent phosphate adsorbed on, and hydroxyl ions released from, hydrous alumina at different phosphate concentrations. From the relationship it is proposed that the phosphate ions are bonded to aluminium atoms forming both monodentate and bridged complexes.

The preparation and properties of the aluminium oxide used have been described elsewhere¹. The sample was predominantly amorphous and had a surface area (B.E.T.) of 197 $m^2 g^{-1}$. The point of zero charge (PZC) pH (ref. 2) was 9.3. The phosphate adsorption and hydroxyl ion release were determined using an automatic titrator³. The adsorption was carried out for 3 h at pH 8.5 in 10 $\mu mol cm^{-3}$ KCl at 30° C under a nitrogen atmosphere. The high pH was chosen so that phosphate in solution existed as divalent ions.

The phosphate adsorption did not reach a maximum (Fig. 1). The theoretical isotherm obtained by using a two-term Langmuir's equation³ was in agreement with the observed adsorption values up to about 280 $\mu mol g^{-1}$, suggesting that at higher values phosphate was adsorbed by different types of sites.

The hydroxyl ions released plotted against phosphate adsorbed (Fig. 2) yielded two straight lines. The ratio of hydroxyl ions released to phosphate adsorbed, R , was 1.44 and 1.07 at less than and greater than 212 μmol of phosphate adsorbed, respectively.

To elucidate the probable mechanism of phosphate adsorption, both the charge characteristic of the oxide solution interface and the phosphate species in solution should be taken into account.

The sign and the magnitude of surface charge on the interface is determined by H^+ and OH^- ions in the absence of other specifically adsorbed anions². At the acid side of the PZC pH the oxide surface can be considered to consist of neutral and positive sites (1).

In the present sample only 40 $\mu mol g^{-1}$ of protons were adsorbed in decreasing the pH from 9.3 (PZC pH) to 8.5.

Considering the great amount of phosphate adsorbed by comparison with the net positive charge, and also the amount of hydroxyl ions released, most of the phosphate was probably adsorbed on neutral sites.

The following ligand exchange reactions can be envisaged for adsorption of phosphate at $< 212 \mu\text{mol}$:

For the reaction as in equation (2) $R = 0$ and for that in equation (3) $R = 1$.

It is probable that the ligand exchange on the neutral adsorption sites is mediated by protons made available by dissociation of the monohydrogen phosphate at the oxide surface⁴. The dissociated form, however, seems to have a transitory existence, for the evidence is that the adsorbed phosphate rapidly acquires a proton from the solvent and equilibrates with the species in solution¹.

The exchange reactions suggested above do not, however, account for R being > 1 . One possible reaction is the formation of binuclear aluminium phosphate complexes with phosphate bridging across unshared corners of adjacent aluminium atoms (4) following the adsorption as in equation (3).

The value of R for the combined reactions of equations (3) and (4) is 2.

Similar models for the presence of a bridging ligand configuration of the adsorbed phosphate have been proposed from phosphate desorption⁵, kinetics of isotopic exchange⁶ and change in surface charge studies⁷. The R value of 1.44 obtained here is probably the result of reactions (3) and (4) and to a smaller extent reaction (2).

Fig. 1 Phosphate adsorption on hydrous alumina. The curve is the theoretical isotherm obtained by using a two-term Langmuir's equation.

At a $\text{pH} \sim 5$, phosphate in solution is mainly present as monovalent ions and is probably adsorbed on hydrous alumina as monodentate ligands¹. With increasing pH the proportion of divalent phosphate in solution, and consequently that adsorbed, will increase resulting in greater amounts of adsorbed phosphate forming ring structure (4). Phosphate held as six membered ring structure can be expected to be more stable than that bonded as monodentate ligands. Hence the lability of the aluminium phosphate complex would decrease with increasing pH . In fact observation to this effect has been made for the isotopic exchange of adsorbed phosphate on goethite⁸. Although the authors explained their results based on acid-base catalysis, disregarding the phosphate species adsorbed, the present results in conjunction with the earlier report¹ indicate that the charge of the phosphate ion also determines the type of bonding of adsorbed phosphate and therefore its lability.

The change in slope of the hydroxyl ion release data observed at $212 \mu\text{mol}$ of phosphate adsorbed (Fig. 2) suggests a different

Fig. 2 Hydroxyl ions released plotted against phosphate adsorbed. The two straight lines are drawn down according to the equations:

$$\text{OH}^- = 1.44(\pm 0.05)\text{P at } \text{P} < 212(\pm 40) \mu\text{mol}$$

$$\text{OH}^- = 1.07(\pm 0.11)\text{P} + 79.3(\pm 33.4) \text{ at } \text{P} > 212 \mu\text{mol}$$

Confidence interval 95%.

mechanism of adsorption at greater values. The fact that the experimental points at high adsorption values deviate from the Langmuir curve corroborates this suggestion.

The change in slope probably indicates disruption of aluminium polymers¹. As the chemical potential of phosphate in solution increases, the phosphate ions will compete with the OH^- that are bridging aluminium atoms (ol groups) and eventually displace them forming ring structure (5).

The calculated value of R for such a reaction is 1.0 which agrees with the observed value of 1.07.

I thank the New Zealand National Research Advisory Council for a fellowship and Mr D. M. Duganzich for statistical analysis.

Reversibility and biological machines

THE application of the traditional, macroscopic arguments of thermodynamics to very small systems (for instance, using individual cross bridges to generate force in striated muscle, which use "one molecule of ATP at a time"¹), has been questioned². It is demonstrated here that they cannot be applied to very small systems without very drastic modification. That is because of the requirements of quantum theory and information theory. The modifications are substantial and inescapable for systems such as individual cross bridges although they become negligible for macroscopic systems.

Consider a machine capable of performing mechanical work. Parallel considerations apply to a device performing electrical work (for example, a fuel cell) but the distinction becomes blurred at the molecular level. For want of a better term I refer to the point of application of the force as the 'piston', although I may be referring to a part of an individual macromolecule undergoing a conformational change. The quantal definition of work, using the Born-Oppenheimer separation of electronic and nuclear motion, has been treated fully elsewhere (B.F.G. in preparation) in a discussion of the quantum mechanics of cross-bridge action.

If the force function is $F(x)$, where x is the position of the piston, then to perform work reversibly, the position of the 'piston' must be measured accurately in order to apply the appropriate external force F_{ex} . Quantum theory and information theory require that a minimum amount of energy is expended in ascertaining position x to within limits $\pm \Delta x$ (where $\Delta x > 0$). The energy cost ΔE is

$$\Delta E \geq hc/4\Delta x \quad (1)$$

according to Brillouin³, where h is Planck's constant and c is the velocity of light. Obviously, ΔE is completely negligible for a macroscopic observation (that is, if Δx is about 1 mm) but for a molecular system ΔE is very important. The uncertainty in the force generated at position x in the process is then

$$\Delta F = F(x) \pm \Delta x(dF/dx) \quad (2)$$

We can assume without loss of generality that $dF/dx < 0$. To perform a reversible extension, we would normally make F_{ex} as close as possible to F (thus ensuring that $F_{ex} = F(x) - |\epsilon|$, with $|\epsilon| \rightarrow 0$ in the limit). Because of the uncertainty the best that becomes attainable is

$$F_{ex} = F(x) + \Delta x(dF/dx) - |\epsilon| \quad (3)$$

The work done by the system is then, in the limit $|\epsilon| \rightarrow 0$

$$W^+ = \int_{x_1}^{x_2} F(x)dx - \Delta x \int_{x_1}^{x_2} \frac{dF}{dx} dx \quad (4)$$

where $F_1 > F_2$ because $x_2 > x_1$. Conversely, in a compression the best that can be attained for the work done on the system is to take $|\epsilon| \rightarrow 0$ in equation (5)

$$F_{ex} = F(x) - \Delta x(dF/dx) + |\epsilon| \quad (5)$$

so that

$$W^- = W_{rev}^- - \Delta x(F_4 - F_3) \quad (6)$$

where $F_4 > F_3$. Clearly, for any cycle involving j steps

$$W = W_{rev} - \Delta x \sum_j |F_j - F_{j+1}| \quad (7)$$

where the correction is always negative. If the net energy input during the cycle is Q , then the conversion factor θ is given by

$$\begin{aligned} \theta &= W/(Q + \Delta E) \\ &= (W_{rev} - \Delta x \sum_j |F_j - F_{j+1}|)/(Q + \Delta E) \end{aligned} \quad (8)$$

By substituting from inequality (1) this gives

$$\theta \leq (W_{rev} - [hc \sum_j |F_j - F_{j+1}|/4\Delta E])/(Q + \Delta E) \quad (9)$$

which can in turn be rearranged in terms of convenient dimensionless quantities α and z

$$\theta/\theta_{rev} \leq (1 - \alpha/z)/(1 + z) \quad (10)$$

where θ_{rev} stands for W_{rev}/Q , that is, the classical conversion factor; the relative or dimensionless energy cost of control

$$z = \Delta E/Q$$

and

$$\alpha = hc \sum_j |F_j - F_{j+1}|/4QW_{rev}$$

For classical thermodynamics, $\alpha = 0$, that is, Planck's constant is considered negligible, and $z \rightarrow 0$ because the energy cost of achieving reversibility is ignored, whereupon $\theta \rightarrow \theta_{rev}$. For quantal or molecular machines the optimum controlled situation can be calculated by differentiating equation (10) with respect to z (α constant) and setting the derivative equal to zero. The result is

$$z_{max} = \alpha(1 + \sqrt{1 + 1/\alpha}) \quad (11)$$

and this gives the maximum possible value for θ/θ_{rev} as

$$(\theta/\theta_{rev})_{max} = \frac{1 - \{1 + \sqrt{1 + 1/\alpha}\}^{-1}}{1 + \alpha\{1 + \sqrt{1 + 1/\alpha}\}} \quad (12)$$

If more energy than z_{max} is used, then α decreases because of the energy cost of information; if less energy than z_{max} is used θ decreases because of the irreversibility (to dissipation, acceleration of the piston and so on).

For a macroscopic amount of gas, for instance, 1 mol, where $F_j \sim 10^5$ N, and $Q \sim 4 \times 10^4$ J, assuming $\theta_{rev} = 0.9$, $\alpha = 3.5 \times 10^{-28}$ and so, from equation (11), $z_{max} = 1.87 \times 10^{-14}$. (It is important to remember that α and z are dimensionless numbers.) The energy cost of optimal control, Qz_{max} turns out to be

7.5×10^{-10} J, and the resulting conversion factor, θ , is within one part in 10^{14} of the classical value θ_{rev} .

For a cross bridge, or for any comparable molecular machine (because the orders of magnitude are not affected by the detailed mechanics of the system), the situation is very different. Using figures quoted by Huxley⁴ $F_j \sim 10^{-12}$ N, $Q \sim 6.67 \times 10^{-20}$ J (the 'ATP quantum' of energy/molecule), and again taking $\theta_{rev} = 0.9$, then $\alpha = 12.37$ and $z_{max} = 25.2$. The energy cost of optimal control now turns out to be 1.6×10^{-18} J, which is 25 ATP quanta: $(\theta/\theta_{rev})_{max}$ turns out to be 0.018.

Clearly, any degree of control tending towards reversibility is out of the question for systems as small as this, as in fact they are known to operate at much higher conversion factors than 0.018, both on grounds of theory (BFG unpublished) and of experiment⁵.

Accordingly the conclusion must be reached that the reversible operation of a machine is not in general optimal for the conversion into work of energy entering into the system, except in the limiting case of macroscopic systems where the energy cost of the necessary control becomes negligible compared with the output per cycle of the machine. Further, the optimal conversion process must, in general, occur at a finite rate and, for very small systems for which $z_{max} > 1$, this rate is uncontrolled and determined by the mechanics (quantum or semiclassical) of the system itself.

For intermediate cases the optimal rate will be determined by a compromise between the free running system and its control. Only in the classical limit, $\alpha \rightarrow 0$, $z_{max} \rightarrow 0$, is the optimal process infinitesimally slow. It is interesting to estimate that the minimum size of machine discernible and therefore potentially controllable, by the ATP energy quantum is given by inequality (1) as $2\Delta x = hc/2\Delta E \geq 1.4 \mu\text{m}$, which is almost exactly the experimental half-sarcomere length in vertebrate striated muscle, generally regarded as the minimum functional unit under the control of the appropriate Z band.

With regard to the statement of the second law of thermodynamics in a form appropriate to molecular machines, Popper⁶ and McClare⁷ have already stated clearly that the problem involved the necessity of defining work at the microscopic or molecular level. This definition, in purely quantum mechanical terms, is the starting point for Gray and Gonda (BFG in preparation) in a programme of the theoretical investigation of biological molecular machines.

It is necessary to discuss the Born-Oppenheimer separation of nuclear and electronic motion, and the Hellmann-Feynman theorem for time-dependent states. Under certain conditions that are well satisfied in biological machines, it is possible to show that the expectation value of the force as calculated from the Hellmann-Feynman theorem is an adiabatic invariant for non-stationary states involving large nuclear displacements (conformation changes). Work can then be defined simply as a path integral in the usual way. In spite of this, the word 'work' is conspicuously absent from every quantum mechanical textbook I have been able to consult.

From this viewpoint (BFG in preparation) it seems clear that a molecular machine, that is, one which must work below the level of profitable controllability, can operate cyclically and repeatedly in one direction only. If it is regarded as the analogue of a 'heat engine', to use a classical term, it cannot be run backwards as the analogue of a 'heat pump' or 'refrigerator' stretching an actively contracting muscle will not cause cross bridges to traverse their cyclic path in reverse to resynthesise ATP (even assuming the used ADP stayed put) without violating this statement. It is a statement at the molecular level parallel to the macroscopic statement that Joule's experiments on the first law of thermodynamics cannot be carried out in reverse, water will not spontaneously cool and lift a weight.

Time to understand pictures and words

WHEN an object such as a chair is presented visually, or is represented by a line drawing, a spoken word, or a written word, the initial stages in the process leading to understanding are clearly different in each case. There is disagreement, however, about whether those early stages lead to a common abstract representation in memory, the idea of a chair¹⁻⁴, or to two separate representations, one verbal (common to spoken and written words), and the other image-like⁵. The first view claims that words and images are associated with ideas, but the underlying representation of an idea is abstract. According to the second view, the verbal representation alone is directly associated with abstract information about an object (for example, its superordinate category: furniture). Concrete perceptual information (for example, characteristic shape, colour or size) is associated with the imaginal representation. Translation from one representation to the other takes time, on the second view, which accounts for the observation that naming a line drawing takes longer than naming (reading aloud) a written word^{6,7}. Here we confirm that naming a drawing of an object takes much longer than reading its name, but we show that deciding whether the object is in a given category such as 'furniture' takes slightly less time for a drawing than for a word, a result that seems to be inconsistent with the second view.

In each of three conditions with different adult subjects, 96 line drawings of objects or their names written in lower case Letraset (Berling 14 point) were presented one at a time in a tachistoscope, preceded and followed by a mask of haphazard lines and pieces of letters. Each subject saw half the 96 items as words and half as drawings, in alternating blocks of 16 items. Each item was presented as a drawing to half the subjects and as a word to the other half. The subject had never seen the drawing before it was presented. The experimenter said ready or (in the third condition) named a category before each presentation, and after an 800-ms interval the item appeared. A voice key was used to measure response time from the onset of the item.

To discover whether the drawings and words were equally discriminable as visual patterns, in the first condition 16 subjects were shown the items for brief durations, 40, 50, 60, or 70 ms. The durations were presented in a random order, permuted across subjects so that each item was shown equally often at each duration. Subjects named or read the items. The estimated exposure duration required to report 50% of the items correctly was 44 ms for the drawings and 46 ms for the words.

In the remaining two conditions items were presented for 250 ms, at a level well above threshold. Subjects in the second condition ($n=8$) named the object or the word aloud, as rapidly as possible. In the third condition ($n=16$) the experimenter named a category before the item appeared. The subject said yes if the item was a member of the category, as it was on half the trials, and said no otherwise. Altogether there were 18 categories containing two to nine items: for example, food (carrot, pie), clothing (hat, coat), tools (pliers, hammer).

The results of the second and third conditions are shown in Fig 1. As in earlier reports^{6,7} drawings took longer to

Fig 1 Mean response time in condition 2 (naming) and condition 3 (matching the item to a spoken category). The white bars are responses to drawings, the black bars, to words. Each bar is based on at least 350 responses, errors and responses that took longer than 2 s (together, less than 5% of the trials) were omitted.

name than words, the mean difference was 260 ms (standard error of the mean difference, 91 ms). The difference was in the same direction for all eight subjects ($P < 0.01$, sign test), and for 93 of the 96 items ($P < 0.001$). In the third condition drawings were categorised faster than words: a difference of 51 ms overall (standard error of the mean difference, 42 ms). The difference was 57 ms for yes responses and 44 ms for no responses. Fourteen out of 16 subjects were faster with drawings than words ($P < 0.01$, sign test). Of the 96 items, 68 were matched faster as drawings ($P < 0.001$).

Recall that the second view of memory asserts that an object has two representations, and that an object's category (a verbal abstraction) is associated with its name and only indirectly with its appearance. If, as that view claims, a drawing must be named implicitly before its category is determined, then in the present experiment one would expect drawings to be categorised more slowly than words^{8,9}, just as they were named 260 ms more slowly. But drawings were not slower than words: they were 50 ms faster. Furthermore, a drawing was categorised much more quickly than it was named, which also makes it unlikely that naming preceded categorising. That finding is, however, not by itself conclusive, since a yes-no matching response may be simpler and so faster than overt naming.

Before one concludes that the second view is untenable, the following four objections must be considered.

(1) Drawings in a given category might have shared certain visual features, so a drawing may have been categorised rapidly on the basis of those features before the subject knew exactly what it was⁹. That is unlikely because the items were chosen to look as diverse as possible, and because at near-threshold durations (first condition) subjects rarely reported a drawing's category but not its name.

(2) Some words (for example, bear, tie, train) were ambiguous, and the first meaning assigned by the subject may not have matched the specified category. An analysis of just the unambiguous items, however, reduced but did not eliminate the advantage of drawings.

(3) Concrete words must be imaged to be categorised—the converse of the naming hypothesis. That seems unlikely, since imaging a word is reported to require at least 0.5 s (ref. 5).

(4) The category of an item is independently associated

to both its name and its appearance. Although our results do not contradict that unparsimonious hypothesis, it would be surprising if a verbal category were more strongly associated with a drawing than a name.

The first view claims that written words and drawings (and presumably also spoken words and objects experienced directly) lead to a common representation in memory, neither word-like nor image-like, and it is that representation which is connected with knowledge of an item's category. In our study, that representation was reached more rapidly from drawings than from words. On this view, naming a drawing is slow because it requires an extra step from the abstract concept to its associated name, whereas naming a word only requires that the word pattern itself be identified¹⁰ and then it may be articulated even before the concept is evoked.

In sum, our results are consistent with the view that knowledge of the category of an object is associated with an abstract idea of the object rather than directly with its name or appearance. Since the name and appearance of an object are also represented in memory, a further question is whether other knowledge one has about an object (such as its typical size or value) is linked to the abstract concept or is directly associated with the name or image. The answer may help to resolve an old question: what are the functions of images and words in thought?

Sex differences in imagery and reading

STANDARD texts on differential psychology often discuss briefly the existence of sex differences in the ability to perform various cognitive tasks^{1–3}. A rough generalisation is that females perform better than males on verbal tasks (for example, verbal fluency, articulation, spelling), whilst males are superior on visuospatial tasks (for example, maze learning or form-board tasks), although exceptions are plentiful. In view of the emphasis in contemporary cognitive psychology on the pervasiveness of verbal coding in a variety of cognitive tasks, and also current interest in such visuospatial abilities as visual imagery or mental rotation, it seems surprising that no attention has been paid to the possible existence of sex differences.

A possible reason for this neglect is that the sex differences observed in psychometric investigations are usually very small, and sometimes unexpectedly absent, as for example in block design tasks, which would seem to be visuospatial^{4,5}. The inability to obtain clear or even consistent sex differences may well be the result of the impurity of the tasks used. Ostensibly verbal tasks such as syllogistic reasoning or counting can be shown to involve visuospatial imagery^{6,7}, and ostensibly visuospatial tasks such as block design could be successfully performed verbally. Consequently a large underlying sex difference in mode of processing would not necessarily reveal

Fig. 1 Percentage of subjects giving the correct response on each task in experiment 1

itself as a sex difference in level of performance in these tasks. A study of the effect of brain damage on performance on the Kohs block design task⁸ illustrates this possibility. In this study, male performance was more impaired by right-hemisphere than by left-hemisphere damage, whereas for females degree of impairment did not depend on site of damage, furthermore, for females with left-hemisphere damage, but for no other group, there was a significant positive correlation between performance on a verbal task (an aphasia battery) and block design performance. This pattern of results is consistent with extensive verbal involvement in block design performance for females but not for males.

What is needed if these issues are to be properly studied are tasks which are purely verbal or purely visuospatial. We used two such tasks in our first experiment. For the verbal task, subjects were asked to proceed mentally through the alphabet from A to Z, counting the number of letters containing the sound 'ee', including E. No external aids such as speaking or writing were permitted. The subjects were asked to perform as rapidly as possible and the time between the beginning of the task and the utterance of the solution was measured. The visual task, performed under the same conditions, was to proceed mentally through the alphabet from A to Z, counting the number of letters containing a curve in their upper-case form. Since no information about the shape of a letter could assist in deciding whether its name contains the sound 'ee', and since no information about the sounds constituting the name of a letter could assist in deciding whether its printed form contains a curve, we considered that these tasks were to a sufficient degree purely verbal and purely visual. The subjects were 75 right-handed undergraduates at the University of Reading, 38 females and 37 males, they were tested individually with both tasks.

Females completed the verbal task more rapidly than males (22.9 s compared with 23.7 s) whilst males completed the visual task more rapidly than females (21.5 s compared with 22.4 s), but this interaction was not statistically significant, because of the very large within-sex individual differences in completion times. A significant effect was, however, obtained in error rates. Surprisingly, many subjects gave incorrect responses, no doubt because they had been asked to perform the task as quickly as possible and were being timed. The percentage of subjects responding correctly to each task is shown in Fig. 1. Significantly more females than males were correct on the verbal tasks ($\chi^2=3.85$, $P<0.05$). Significantly more males than females

were correct on the visual task ($\chi^2=6.50$, $P<0.05$). The sex difference in error rates is quite large, for both tasks.

To determine whether such marked differences are confined to tasks involving imagery, we next used a task developed by Corcoran⁹. He found that subjects asked to scan through a passage of prose crossing out all occurrences of the letter 'e' overlooked unpronounced e's (as in 'late') much more often than pronounced e's (as in 'let'). This indicates that both verbal and visual analysis is occurring in this apparently visual task. If females rely strongly on verbal analysis, and males on visual analysis, then females should have more difficulty than males in detecting unpronounced letters, since verbal analysis cannot detect such letters. We used 10 male and 10 female undergraduates and asked each to scan through six photographically enlarged pages from novels, crossing out all occurrences of the letter 'h'. They were given 2 min for each page, with 2 min rest between pages. The results are shown in Fig. 2. For pronounced targets, there was a negligible difference between male and female miss rates; for unpronounced targets, female miss rates were much higher than male miss rates. This interaction between target type and sex was significant ($F=4.15$, $P<0.05$) as was the main effect of target type ($F=6.97$, $P<0.01$) and sex ($F=25.50$, $P<0.01$).

This result implies that phonological coding during reading is more prevalent in women than in men, and this was investigated more directly in our third experiment. If we use the term 'internal lexicon' to refer to the stored body of knowledge concerning the words of the language, and the term 'lexical entry' to refer to a subset of the information referring to a particular word (information about how the word is spelled, how it is pronounced, what it means and so on), then the task in visual word recognition is to extract information from a visually presented sequence of letters, and to use this information to locate the lexical entry belonging to the word being viewed (for example by searching the lexicon for an entry containing this information). Given this theoretical framework, we can ask what the nature of the information is. An enduring conflict in the study of reading has been between those who consider that the information is visual and those who consider that it is phonological, that is, that a letter sequence is converted to a phoneme sequence (using a system of grapheme-phoneme

Fig. 2 Miss rates in experiment 2

correspondence rules) before lexical access. There is evidence in favour of both views, this conflicting evidence can be reconciled by proposing that both forms of access are used, simultaneously and independently, and that whichever system locates the required lexical entry first is responsible for word recognition on that particular occasion. Given this, we might expect a sex difference in the relative efficacy of the two systems, word recognition mediated by phonological encoding might be the predominant method of lexical access for women, and visually-mediated word recognition might be the predominant method for men.

We investigated this by using a lexical-decision task¹⁰. On each trial in this experiment, the subject was presented with a row of letters and asked to press a YES key as quickly as possible if the stimulus were an English word, otherwise to press a NO key. The stimuli were presented on an oscilloscope screen controlled by a PDP-12 computer, which also measured the time between display onset and response, recorded which response was made, and printed a data analysis at the end of each subject's session. The subjects were 10 male and 10 female undergraduates and research students at the University of Reading.

A total of 156 letter sequences was presented, in a different random sequence to each subject. Of these, 39 were homophonic words, that is, for each of them there existed another English word with the same pronunciation and a different spelling (for example, SUITE, PAWS or URN), 39 were non-homophonic English words, each matched with one of the homophones on number of letters, number of syllables, word frequency and part of speech, 39 were homophonic non-words constructed so that for each of these non-words there existed two English words with the same pronunciation but different spellings (for example, HORL, LAKS, or THROO), and 39 were non-homophonic non-words, each derived from one of the homophonic non-words by changing one letter so that the resulting letter sequence was still perfectly pronounceable but was not pronounced like any English word.

If access to the internal lexicon is ever phonological, it will be more difficult to say NO to HORL than to DORL, since the phonological system will incorrectly locate a lexical entry in the case of HORL but not in the case of DORL¹⁰. Furthermore, if phonological access is more prevalent in women than in men, then the difficulties engendered by homophonic non-words such as HORL should be more severe for women than for men.

Mean latencies for correct NO responses were 578 ms for men and 737 ms for women when homophonic non-words were used, and 545 ms for men and 647 ms for women when non-homophonic non-words were used.

The NO response was thus slower for non-words which sounded like English than for those which did not. This was true for every one of the twenty subjects. The effect was larger for women than for men (33 ms compared with 90 ms), and this difference was statistically significant (Mann-Whitney $U=23$, $P<0.05$). In the case of words, response latency was not influenced by whether or not a word was a homophone, the only significant effect was that women were about 100 ms slower than men in responding YES to words.

The results with non-words indicate that phonological access to the lexicon is used to some extent by both sexes, but more by women than by men. If phonological access is completed before visual access more often in women than in men (for example, because women are more efficient or faster than men at applying phonological rules to letter sequences), the sound of the word will have more effect on women than on men, as was the case.

Whether these sex differences are present early in life remains to be determined, but if the same pattern of sex differences appears in young children, this finding may have educational implications. For example, it may prove efficient to teach girls to read by a phonological method ('phonics') and boys to read by a visual method (for example, the 'whole-word'

method). Some of the sex differences in cognition discussed earlier may in fact be present very early in life^{2,11}. Furthermore, male superiority in spatial tasks is evident in rats as well as men¹¹, and seems to be susceptible to hormonal influences in rats and in men^{11,12}. If relatively pure tests of visual and phonological processing, such as those used in experiment 1, can be devised which are suitable for use with children before they learn to read, it may be possible to obtain satisfactory evidence concerning the origins of the sex differences in cognition described in this paper.

A model illustrating the importance of timing in the regulation of breathing

THE effectiveness of afferent volleys from arterial chemoreceptors in stimulating inspiration depends on the precise timing of their arrival within the central nervous system^{1,2,16}. Torrance¹ suggested that variation in the degree of mismatching of the actual with the optimum timing of volleys would provide an extra element of fine control in the respiratory system. I have developed a scheme which is based on this suggestion and also on the following experimental observations.

(1) In the cat the afferent impulses from chemoreceptors are grouped in bursts the peaks of which correspond in time to the middle of the rising phase of the oscillations of carotid arterial P_{CO_2} (refs 3 and 4), peak afferent discharge should thus be related to mid-expiration, the two events being separated in time by the lung-to-carotid body circulation time, itself relatively constant under a single set of circumstances, and in normal men commonly occupying the duration of nearly two respiratory cycles⁵.

(2) A burst of chemoreceptor discharge in the cat is only effective in augmenting inspiration if it falls within a certain part of the cycle, the period of central inspiratory excitability (PCIE), which is closely related to inspiration itself. Inspiration cannot be excited by this pathway during the rest of the cycle, the system behaving as if memory is short^{1,2}. Afferent volleys arriving outside the PCIE do, however, prolong expiration^{1,16}.

(3) In man, the respiratory system is capable of detecting differences in the alveolar P_{CO_2} time profile so brief as to occupy only one-third of the whole cycle. This property is almost certainly mediated by arterial chemoreceptors⁶.

(4) Also in man, with changes in chemical drive from any source, tidal volume (V_T) and the duration of expiration (T_E), and hence total cycle duration (T_T) are inversely related⁷. The inverse relation holds good on a breath-by-breath basis⁸.

A crude model has been constructed (Fig 1) using squared paper and following some arbitrary quantitative rules: (a) initially steady eupnoeic inspiration and expiration occupy 1 and 2 s respectively, (b) PCIE coincides exactly

with inspiration, (c) the afferent volleys also last for 1 s, (d) a volley stimulates inspiratory volume and shortens expiratory duration in proportion to the overlap between it and PCIE, and (e) with no overlap the volley is ineffective, inspiratory volume is decreased and expiratory duration lengthened from the eupnoeic values. In these circumstances, the residual ventilation is prevented from falling below 70% of the eupnoeic level by the slowly-acting central drive from (CO_2 , H^+)

In cases 1 and 2 (Fig 1) the lung-to-carotid body circulation time is such that, with the initial steady breathing, the burst of afferent impulses follows the PCIE of the next-but-one respiratory cycle and overlaps it by one-fifth. In cases 3 and 4 the circulation time is lengthened so that the afferent burst is delayed sufficiently to overlap the PCIE of the next-but-two eupnoeic cycle, the overlap, however, although again one-fifth, is reversed and the burst precedes the PCIE.

After four steady eupnoeic cycles (Fig 1) an extrinsic irregularity, comprising a long (cases 1 and 3) or short (cases 2 and 4) breath, disturbs the rhythm, such irregularities occur continually in normal human breathing⁹⁻¹¹. The regular time-base provided by the spacing of the afferent bursts is not disturbed until two cycles later, but the overlap between the bursts and the PCIE is altered after only one cycle, the consequences for \dot{V}_T and T_E depend on the circumstances (Fig 1).

In cases 1 and 2, after the disturbance, a large breath of short duration alternates with one or two small breaths of long duration but the alternation of the overlap between afferent bursts and PCIE is such that correction by the timing mechanism is towards the mean, and regularity (case 2), or regular non-uniformity (case 1), of the time base is quickly re-established. Over two or three cycles in cases 1 and 2, respectively, the mean quotient $\dot{V}_T/(T_I + T_E)$, (=mean ventilation, \bar{V}) remains at the predisturbance value. In other words, negative feedback results and overall stability of ventilation is achieved.

On the other hand in cases 3 and 4 (afferent bursts preceding PCIE), the initial steady eupnoea turns out to be unstable. After an extrinsic long breath (case 3), PCIE falls so far behind the afferent burst as to lose touch completely and the mean ventilation stabilises at the minimum value of 70% of eupnoea, the time-base is slowed and is incapable of reversing the situation. After an extrinsic short breath

(case 4), the burst-PCIE overlap is increased and the next breath is also shortened. A complex oscillation of response ensues, with the pattern repeating every six breaths, the time-base is irregular, mean ventilation settles 33% above the eupnoeic value and the time relation between burst and PCIE may reverse. Although the details of the pattern depend on the numerical values assumed, the general features are found with most of the likely combinations. Cases 3 and 4 exhibit an element of positive feedback, limits being set by the maximum and minimum possible effectiveness of the chemoreceptor drive under the prevailing conditions of blood-gas tensions.

Models of this type are consistent with a number of observable phenomena of normal human breathing. The enhancement of hypoxia sensitivity in even mild exercise¹² in the absence of any increase in the average impulse frequency in the chemoreceptor afferents¹³, could be due to 'sharpening' of the grouping of impulses into bursts. Stability of ventilation would, however, require that the PCIE precede the bursts, as in cases 1 and 2.

At low ventilations, T_E varies much more with small changes in \dot{V}_T than when ventilation is high⁷. The model would thus predict the well-known irregularity of breathing in the short term during eupnoea, especially when inhalation hypoxia is present. It also predicts the greater regularity when ventilation is stimulated by CO_2 inhalation, although other factors are certainly involved here.

In the periodic breathing of high altitude the period of the swing is about 0.75–1 min, a time more appropriate to the slow, well-damped negative-feedback loop involving the intracranial (CO_2 , H^+) receptor system, than to the fast, poorly-damped loop involving peripheral chemoreceptors. The latter, however, is an essential component as its inactivation by breathing oxygen abolishes the periodic breathing. A scheme like that of cases 3 and 4 would resolve the paradox with the afferent bursts preceding PCIE, a slight disturbance would promote the maximum or minimum situation, with ventilation and metabolism mismatched. Correction of the mismatching by the central (CO_2 , H^+) loop would have a long time constant but the correction itself would activate the peripheral loop which, by positive feedback, would quickly flip the whole system over into the other extreme state. Periodic breathing is most marked in recumbency, especially in sleep, during which lung-carotid circulation time is slightly lengthened and there are few

Fig. 1 The timing model simulated time relation between respiratory movements, scaled to percentage of control, and chemoreceptor bursts of activity. Inspiration upwards (bold lines) with four steady eupnoeic cycles at left of each line. Afferent volleys (rectangles) last 1 s and each is connected by dashed line to the middle of the expiration (downward arrow) that initiated it. Volleys only stimulate inspiratory volume and flow, and shorten expiratory duration when they overlap PCIE, which coincides with duration of inspiration. The degree of overlap is indicated by blackening of the volley symbols: + $\Delta 0.2$ s of overlap results in a + $\Delta 20\%$ tidal volume and - $\Delta 20\%$ expiratory duration. Inspiratory duration (1 s) is unaffected. With no overlap, chemoreceptor bursts are ineffective and central respiratory drive prevents ventilation from falling below 70% of eupnoea. Cases 1 and 2: circulation time is 4.8 s, that is, slightly less than the duration of two respiratory cycles, thus volley overlaps PCIE from behind. An extrinsic long or short breath initiates changes in overlap which do not change mean ventilation, \bar{V} , although in the absence of damping in the model the short term hunt would continue indefinitely. Cases 3 and 4: circulation time is 6.2 s, that is, slightly longer than the time for two respiratory cycles, thus volley overlaps PCIE from in front. An extrinsic long or short breath is followed by changes that reveal the intrinsic instability. In case 3, the time-base provided by the volleys is lengthened and mean ventilation falls. In case 4, the volley-PCIE overlaps vary widely, breathing is irregular and mean ventilation high. These states continue until corrected by slow changes in the central drive, over-correction and longer term hunting are likely to occur.

irregularities to disturb the hunting pattern, although other factors are probably involved. It is also possible that some pathological states result from disorders of the mechanism described.

The model is clearly over simplified: thus PCIE and the afferent bursts have been given duration but not intensity. The time profile of the PCIE might resemble that of the phrenic neurogram and the profile of the bursts is probably like a skewed sine wave⁴. The bursts could also vary in amplitude, and rhythmic or periodic cardio-respiratory events could affect the transit times of the blood-gas oscillations from lungs to receptors. Further developments will require more sophisticated computation.

An important feature of the mechanisms whereby phasic afferent activity could produce the effects described is that there should be little or no central memory of earlier bursts, this could be achieved if the connections were very simple. Indeed, Davies and Edwards¹⁴ found few synapses between the incoming fibres and the central inspiratory neurones. The nature of the effect on T_E is not known. Clark and Euler¹⁵ report that induced changes in V_T lead to changes in T_I , which they regard as being linked to T_E . In man, however, T_E may respond to changes in chemical drive while T_I remains constant⁷.

The relative contribution of the mechanism to short term regulation in normal man at rest at sea level is probably small and possibly even trivial^{5,12}. During exercise, however, 'sharpened' bursts of afferent activity could provide a back-up device such that if ventilation, and particularly its frequency component, were to fall momentarily below the requirements of metabolic exchange, both would receive an extra 'push from behind' so that the proper separation between afferent burst and PCIE would rapidly be re-established.

PTC taste blindness and the taste of caffeine

TASTE thresholds for the bitter substance PTC (phenylthiourea or phenylthiocarbamide) and related compounds containing the grouping

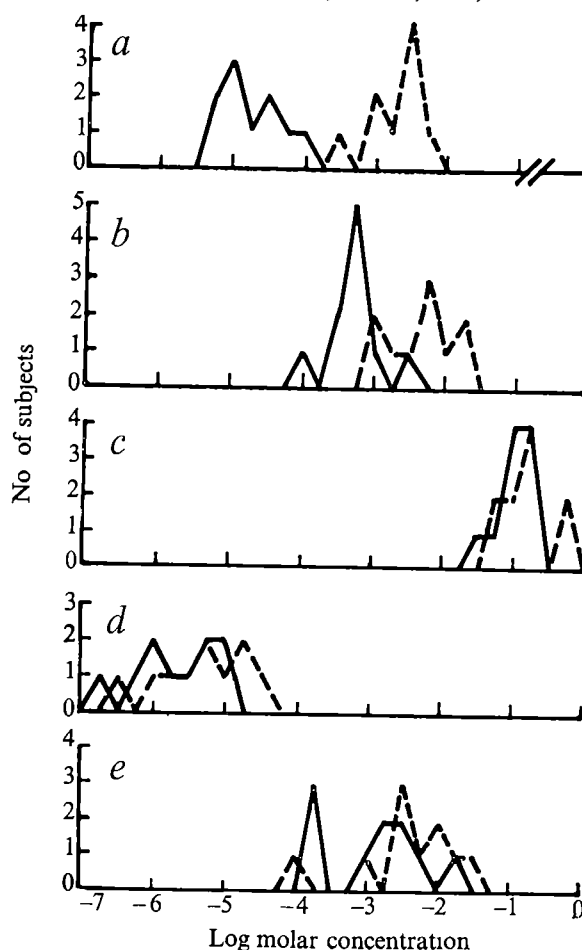

(HNCS) show a bimodal distribution, leading to the designation 'tasters' for the more sensitive individuals and 'non-tasters' or 'taste blind' for the less sensitive. Genetic and population studies have generally attributed this to a simple Mendelian dominance system in humans, non-human primates and some rodent species. All other bitter and non-bitter compounds tested so far have produced Gaussian distributions of thresholds^{1,2}. We have found now, however, that sensitivity to the taste of PTC predicts sensitivity to caffeine, a common bitter substance that lacks the HNCS grouping. This was shown by

threshold measurements and magnitude estimation of supra-threshold concentrations.

We tested ten non-tasters (the first ten undergraduates uncovered by a rough PTC threshold screening procedure) and ten tasters. Each subject's threshold was measured for each of five compounds: PTC, quinine hydrochloride (QHCl), urea, caffeine and sodium chloride (NaCl). The method was a modified Harris-Kalmus procedure³ in which the subject was given eight cups, four contained water (Hydro Service ultrapure water with resistance greater than 18 MΩ cm⁻³) and four contained a particular concentration of the substance under evaluation. The subject rinsed his mouth thoroughly with water before sampling from each of the eight cups which he sorted into two groups: those with a taste and those without. The concentration was decreased successively by 0.25 log steps until the subject failed to sort correctly.

Suprathreshold concentrations were flowed on to the extended tongue at a rate of 4 ml s⁻¹ through a McBurney gravity flow system⁴. The stimuli were always preceded by a 20 s water rinse and were presented, twice each, in random order. Subjects were asked to assign numbers proportional to the perceived intensities of the stimuli⁵. For example, if the first stimulus was judged '10 bitter' and the second stimulus seemed twice as intense, then it was to be judged '20 bitter'. Solutions in both phases of the experiment were warmed to 34°C. Since NaCl and PTC sensitivity are not related, judgments of the bitter substances were expressed relative to NaCl in the following way. The geometric mean of the magnitude estimates for the four NaCl concentrations was obtained for each subject. This mean for each subject was made equal to ten by multiplying with an appropriate factor. The subject's magnitude estimates of the bitter substances were then multiplied

Fig 1. Harris-Kalmus thresholds for PTC (a), caffeine (b), urea (c), QHCl (d), and NaCl (e) for tasters and non-tasters of PTC. *One subject was unable to taste even 0.018 M PTC, the highest concentration used. —, Tasters; ---, non-tasters.

by the same factor. This transformation had no effect on the ratios among magnitude estimates. It merely decreased variability contributed by the absolute size of numbers chosen by the subjects.

Figure 1 shows the thresholds for tasters and non-tasters of PTC. The bimodal distribution for PTC with peaks at 0.00001 M and 0.003 M PTC is typical. The bimodal distribution that resulted for caffeine, however, has not been reported before. Even more interesting, the caffeine thresholds were correlated with the PTC thresholds (Spearman rank correlation coefficient = 0.83, $P < 0.001$). None of the other substances produced a clear bimodal threshold distribution nor were the thresholds correlated with those for PTC.

Fig 2 Perceived bitterness of PTC (a), caffeine (b), QHCl (c), and urea (d) for tasters and non-tasters of PTC. ●, Tasters; ○, non-tasters

Figure 2 shows the perceived bitterness of suprathreshold concentrations of PTC, caffeine, urea and QHCl for tasters and non-tasters of PTC. The functions for PTC show the large difference in sensitivity between tasters and non-tasters to be expected from the PTC threshold results. The functions for caffeine also confirm the lesser difference between tasters and non-tasters shown by the caffeine threshold results. The difference is, however, restricted to the lower concentrations (t tests, $P < 0.01$ for 0.056 to 0.03 M caffeine). The steepened slope of the non-taster caffeine function is reminiscent of the recruitment of loudness in typical nerve deafness⁶. At sufficiently high concentrations, the two PTC functions might meet as the caffeine functions do, however, this possibility cannot be tested because of the limited solubility of PTC.

The lower concentrations of urea were also perceived as slightly less bitter by the non-tasters (t tests, $P < 0.01$ for 0.1 and 0.18 M urea). This suggests that the taste of urea, like that of caffeine, may be related to the taste of PTC even though the peaks of the urea threshold distributions for tasters and non-tasters cannot be resolved. Neither caffeine nor urea contains the HNCS grouping. There are many bitter substances that have not been examined for possible connection with PTC sensitivity, so it now seems likely that there must be others that will also taste less intense to PTC non-tasters.

Beidler and Gross⁷ have argued that current knowledge about the nature of taste receptor sites leads to the conclusion that "there exists no single receptor site peculiar for all molecules representative of any particular taste quality". Our psychophysical results add evidence for the existence of at least two receptor sites underlying the taste of bitter, with the 'PTC site' largely absent in non-tasters and the 'quinine site' present in

both tasters and non-tasters of PTC. Caffeine and possibly urea seem to stimulate PTC sites. This interpretation is also supported by cross-adaptation results reported by McBurney and colleagues. Adaptation to QHCl does not substantially reduce the bitterness of PTC (ref. 8) although among sweet, sour and salty substances, cross-adaptation is virtually complete^{9,10}. That is, adaptation to a substance of one of those qualities reduces the taste intensity of other substances of the same quality.

The possibility of multiple receptor sites underlying a single taste quality poses an interesting problem in sensory coding. Why should PTC and QHCl both taste bitter if they are coded by different receptor sites? The cross-fibre patterning hypothesis^{11,12} gives one answer. Both substances may stimulate largely the same population of nerve fibres even if the receptor sites by which they accomplish this stimulation are different. That is, quality is determined by the pattern of neural activity received by the central nervous system.

A series of earlier studies seemed to support the conclusion that a taster needed his own saliva to taste PTC¹³⁻¹⁶. In the classic study, Cohen and Ogden¹⁵ dried the tongues of tasters with air from an atomiser. Although this procedure rendered their tasters insensitive to PTC, it also rendered half of their control subjects insensitive to saturated solutions of saccharin and salt. They concluded that "saliva aids in many taste sensations" but they could have concluded instead that air drying the tongue interferes with normal taste perception. In all phases of our experiment, PTC was tasted after a thorough water rinse. Our threshold values are similar to those obtained without a rinse condition^{1,16}. We conclude that saliva is not crucial to the ability to taste PTC.

One implication of our results concerns the bitter taste of caffeine in coffee. Coffee tastes bitter because it contains several bitter constituents. The concentration of the caffeine in an average cup of brewed coffee, 0.003-0.004 M caffeine¹⁷, is below or near the threshold of most non-tasters but above the threshold of most tasters. Caffeine cannot, therefore, add a significant amount of bitterness to the already bitter taste of coffee for the non-taster of PTC. It may or may not add some bitterness for tasters depending on the intensities of the other constituents. Fisher and Griffin¹⁶ have shown that taste sensitivity to some bitter compounds is correlated with systemic pharmacological sensitivity. It would be particularly interesting to see if taste sensitivity to caffeine predicts sensitivity to the pharmacological effects of caffeine as a stimulant.

Processing of positional information in the human visual system

CONTOURS seem to be shifted away from the edge of a previously seen figure. Ganz¹ considered this apparent displacement to be caused by lateral inhibition between the contours of an after image of the inducing figure and the test figure itself

Similarly, two lines of different orientation that are presented simultaneously seem to be displaced from one another in orientation. To account for the perceptual expansion of acute angles Blakemore, Carpenter and Georgeson² postulated a superposition of excitatory and inhibitory distributions of activity among the population of orientation detectors in the visual cortex. Superposition would cause the peaks of the distributions to be shifted slightly apart and hence cause the brain to deduce that the angle is larger than it is

Two parallel lines at threshold facilitate each other when they are separated by less than say 2.5', whereas inhibition occurs for larger separations up to about 10' (ref 3). A line weighting function may be computed from the change of increment threshold for one line as a function of separation from the additional line. The shape of this function compares fairly well with other estimates of the spatial extent of excitatory and inhibitory interactions in the light-adapted fovea.

Line weighting functions may be tentatively ascribed to the combined spread of excitation and inhibition among line detectors. Kulikowski and King-Smith⁴ presented evidence that there exist line detectors which are distinguishable from grating detectors, the 'grating sensitivities' of the two detectors as revealed by subthreshold summation are different. This result receives support from the observation that frequency selective preadaptation of line detecting mechanisms shows no interocular transfer as it is found following adaptation of grating detecting mechanisms⁵. Repulsion between parallel lines separated by less than 10' would then be expected by analogy with the model of Blakemore *et al*. We performed an experiment to test this prediction

The stimuli were two parallel, vertical lines, which were 1° long and 1' wide at a viewing distance of 114 cm, presented on a 6° square background, which had a luminance of 36 cd m⁻² (Fig. 1). The position of the inducing line (I) was set by the experimenter, after which the observer adjusted the horizontal position of a pair of 1' diameter lights, which were 0.5° above and below the test line (T), until they appeared to be aligned with T

The observer, whose position was stabilised by a chin rest, was allowed to inspect freely the test field during his observations. Starting alternately from different directions, it usually took the subject seconds to set the dots. He gave two readings

Fig. 1 Stimulus configuration: the separation between the test line T and the inducing line I was set by the experimenter. The subject had to assess the position of T by aligning the dots and the line

for each position of a series of increasing or decreasing line separations. The procedure was repeated in reverse order. Thus four values were obtained for each position of I in one experimental session

Contrary to expectation, no displacement effects were obtained when test and inducing lines were of equal luminance (Fig. 2a and b). But, for line separations of less than 10' of arc, when the luminance of I was higher T seemed to be displaced towards I (Fig. 2c). An exploratory experiment revealed that this attraction increases monotonically as the luminance difference between inducing and test line increases. For larger separations of the lines one of the subjects (IR) produced two data points with significant ($P \leq 0.05$) values of repulsive displacement whereas the data of another subject (WG) do not show any effect. Standard errors are of the order of magnitude that is to be expected when using an alignment criterion

The basic findings of our experiment have been confirmed

Fig. 2 Changes in apparent position of test line T against distance between T and inducing line I. a, Both lines 0.6 log units above threshold, b, both lines 1.6 log units above threshold, c, test line 0.6 log units, inducing line 1.6 log units above threshold. ●, subject, IR, ○, subject WG. Negative values of displacement mean repulsion at negative values of position (I left of T) and attraction at positive values of position (I right of T). Apparent position of T in absence of I is taken as reference value. Vertical bars \pm s.e. ($n = 12$). Dashed lines indicate \pm s.e. of reference value ($n = 24$). Vertical shaded areas denote where the lines could not be resolved

for two other subjects. To investigate possible influences of the configuration of the comparison stimulus we also performed measurements using a vernier alignment criterion. The vernier line had a length of 1° and was positioned 0.5° below T. The results of this experiment were indistinguishable from those of the main experiment.

Purely attractive displacements such as those observed in our experiment are readily explained by the model of Blakemore and colleagues, if it is assumed that only excitatory components interact for the assessment of position. But an appreciable shift occurs only if the individual distributions differ considerably in height. The lower peak is then displaced toward the larger one, provided that the separation of the lines is not too large. To account qualitatively for the observed range of interactions (about 10'), it must be assumed that the spread of excitatory activity is wider than the centre of sensitivity functions that are derived from threshold measurement³.

Though there are no inhibitory interactions in the assessment

of position, two lines separated by several minutes of arc clearly inhibit each other. A control experiment using the same apparatus showed that both subthreshold and superthreshold inducing lines raise the threshold for the detection of a test line located 6' away. This suggests that lateral inhibition participates in the neural analysis of contrast (for example, threshold detection) but not in that of position. Thus we are led to the conclusion that the detection of line stimuli and the neural evaluation of their position are performed separately in the human visual system. This receives support from the finding⁵ that the accuracy for positional judgments is an order of magnitude less than the accuracy for shape or orientation discrimination, for which virtually all the information available at the retina is used.

Hubel and Wiesel^{6,7} advanced the idea of an hierarchical organisation of the visual system suggesting a convergence of cortical simple cells on complex cells whose positional selectivity is poor. Psychophysical line detecting mechanisms may be correlated with the activity of monocularly driven simple cells³. If the hierarchical model is correct, the tapping of positional information before the convergence of the output of these cells on complex cells would be necessary to prevent the loss of that information.

Our data are not easy to reconcile with the general conclusion of Ganz¹ that parallel contours repel each other when they are brought close together. By this principle Ganz explained an important class of geometrical illusions (for example, Poggendorff, Hering, Zoellner). Our results do not support this hypothesis as we found no displacement at all for parallel lines of equal brightness.

We thank Drs Adriana Fiorentini and C R Cavonius for discussions and Miss E Erl for technical assistance.

Retinotectal mismatch: a serendipitous experimental result

THERE is increasing evidence to indicate that neurones are capable of making connections with sites other than those with which they normally connect¹⁻⁵. During an experiment to test the effect on the retinotectal projection of upsetting the normal sequence of innervation of the growing optic tectum by a growing eye in *Xenopus*⁶, we observed, unexpectedly, a result in one animal which could shed some light on a current controversy concerning the manner in which the formation of selective synaptic connections may be controlled. Because this result was fortuitous and because it is difficult to replicate the exact experimental situation we report the result here.

The right eye had been removed at stage 29 (ref 7), before the eye had differentiated, and the animal grew up with only one eye, the left, which innervated the right optic tectum. Two months after metamorphosis the left optic nerve was exposed and cut in the region where the optic chiasma would have been in a normal animal. The optic fibres were then deflected to feed directly into the left optic tectum by placing a small piece of Millipore filter in a midline position. The filter was successful in forcing fibres from the whole eye to innervate the ipsilateral (left) tectum, but it did not

prevent some optic fibres from regrowing to the contralateral (right) tectum. In most cases fibres from the whole eye grew directly to both tecta, as shown by electrophysiological mapping of the retinotectal projection 6 months after the deflection of the optic nerve.

In one animal, however, a most intriguing result was obtained (Fig 1). The projection from the left eye to the left tectum showed the whole nasotemporal extent of the superior visual field covering the dorsal tectal surface—the map was essentially a normal contralateral map, now occurring on the ipsilateral tectum because of the deflection of the optic fibres into this tectum. The same left eye also projected directly to the right optic tectum but in this case the field projection involved only the temporal half of the superior visual field, yet this half-field projected across the whole extent of the dorsal surface of the right tectum. Fibres from only the nasal half of the retina of the left eye seem to have surmounted the millipore barrier and established contact with the right tectum. These nasal retinal fibres (equivalent to the temporal field) in the normal animal occupy only the caudal portion of the tectum and in this animal they occupied only the caudal area of the left tectum. Yet, fibres from this same nasal retina spread their connections across the entire rostrocaudal extent of the right tectum.

Fig. 1 The projection of the left visual field on to the right and left optic tectum. *a*, The two tecta seen from above, *b*, perimetric charts of the left visual field. The animal should be considered as sitting behind the chart, which covers the visual field from the fixation point out to 100° radially. The numbers on the tectal diagrams represent electrode positions and the numbers on the perimetric chart indicate corresponding field positions. S, Superior, I, inferior, N, nasal, T, temporal.

There have been two different explanations offered to account for previous experimental situations in which half of the retina had been observed to spread its projection over the entire tectal surface⁸⁻¹². One suggestion was that following the operation the nature of the remaining half retina changes and the cell labels which are believed to be responsible for selective neuronal connections^{13,14} are altered. The range of such labels normally associated with a whole retina may thus come to reside in the remaining half retina and this could be the reason that fibres from such a partial retina spread over a whole tectum. An alternative view^{12,15} of the manner in which neurones interconnect argues that the molecular interactions between neurones are essentially competitive, such that the presynaptic fibres compete for the available postsynaptic space.

* On this view the fibres from a half retina might be expected to innervate a complete tectum even though the cell labels in the half retina had not changed

We have here a situation where a half retina, which, because it is half of a known normal eye, should have undergone no reorganisation of its cellular labels, innervates a tectum and covers its whole rostrocaudal extent. This finding constitutes support for the competitive variant of the neuronal specificity theory, in which cellular labels do not, of themselves, determine the tectal site at which a retinal fibre will synapse, but rather fix the relative position within the pre- and postsynaptic arrays that the fibre will adopt. We conclude, therefore, that half a retina which undergoes no reorganisation of its neuronal specificity labels may yet spread its connections in order over an entire tectal surface. Our suggestion that specified neuronal arrays produce selective neuronal connections by a process of competition seems to be supported.

Re-establishment of functional connections by regenerating central adrenergic and cholinergic axons

AFTER lesion of their axons, central monoamine-containing neurones have a high capacity for regenerative sprouting^{1–4}. This is observed after a mechanical or electrolytic lesion in the brain or the spinal cord as a development of numerous newly-formed axon sprouts extending from the proximal ends of the lesioned axons. These regenerating sprouts can grow to considerable distances, for example, along myelinated fibre tracts and intracerebral vessels^{1–3}. After selective destruction of the serotonin-containing neurones in the central nervous system (CNS), induced by the neurotoxic drug 5,6-dihydroxytryptamine, the serotonin axons regenerate efficiently and in these favourable conditions it has been possible to demonstrate that lesioned central axons can grow back to their original sites of termination⁴.

With the fluorescence histochemical technique the remarkable regenerative capacity of adult central monoamine neurones is also revealed when lesioned noradrenergic neurones are allowed to 'reinnervate' a transplant of peripheral tissue placed in the brain or spinal cord^{2,3}. In this experimental situation the regenerating central noradrenergic sprouts will reconstitute a terminal pattern in the surviving parts of the grafted tissue that closely mimics its original peripheral noradrenergic innervation. Interestingly, this property does not seem to be unique for the noradrenergic neurones in the brain, in that also presumed central cholin-

ergic neurones have recently been found to have very similar regenerative characteristics (our unpublished observations).

Although the regenerated terminal networks are long lasting, microscopical techniques have not yielded any information as to whether the regenerated central axons reform functional synaptic contacts. We have investigated this question in transplants of the portal vein 'reinnervated' by central noradrenergic and cholinergic neurones in the rat brain. We now report that the regenerated central axons form functional connections with the smooth muscle cells in the transplant. To our knowledge this is the first time a re-establishment of functional connections has been demonstrated after axonal regeneration in the adult mammalian brain.

The experiments were carried out on adult female Sprague-Dawley rats (180–200 g body weight at the time of transplantation). Homologous transplantations of the portal vein to the caudal diencephalon were performed by free hand as described previously for transplantations of other tissues^{3,5}. All recipient animals were subjected to cranial sympathectomy through bilateral extirpation of the superior cervical ganglia to exclude any possible interference by peripheral sympathetic fibres in the transplant. Sections of the portal vein, about 7–8 mm long, were opened by a longitudinal cut and the whole or half of the circumference was used. The portal strip thus obtained was placed vertically in the caudal diencephalon of the recipient rat, extending dorsally through the hippocampus and the corpus callosum³. Transplants of the iris which were placed in this position have previously been found to be invaded by regenerating central noradrenaline (NA)-containing and acetylcholinesterase (AChE)-positive fibres (ref. 3 and our unpublished work).

At 25–30 d after operation, the animals were killed by decapitation under light ether anaesthesia. The transplant was removed from the brain and mounted for combined isometric recordings and electrical field stimulation in a 50 ml organ bath as described previously^{6,9}. The buffer was a modified, oxygenated Krebs solution⁹ kept at 38°C throughout the experiment. After an accommodation period of 15–30 min, during which the spontaneous myogenic activity of the transplant was registered, the contractile responses to electrical field stimulation and to exogenous application of neurotransmitters (NA and acetylcholine (ACh)) were studied. Field stimulation was done with square wave impulses of 15 V amplitude between the electrodes (5 mm apart), 10 ms duration, and 6 or 10 Hz. The stimulation was applied for 1 min periods at intervals not less than 5 min. NA or ACh was added to the bath to a concentration of 10⁻⁶ M, and was washed out after 1–2 min. Spontaneous activity was allowed to recover between the responses to drugs or field stimulation. The effects of NA and field stimulation were tested before and after applications of the α -adrenergic blocker phenoxybenzamine (PBZ) (Dibenzylamine, Smith, Kline and French, 10⁻⁶ M) and this was followed by a similar second sequence of experiments comprising exposure to ACh and field stimulation before and after the application of atropine sulphate (10⁻⁶ M). On some of the investigated transplants the experiment was done in the reverse order, that is, starting with the cholinergic receptor blockade, followed by the adrenergic blockade.

The regeneration of NA-containing and AChE-positive nerves into the portal transplants was investigated microscopically with the Falck-Hillarp fluorescence method¹⁰ and then with the Holmstedt¹¹ modification of the Koelle method for AChE, respectively. In the AChE-staining, incubation time was 4–6 h and Mipafox (4 × 10⁻⁶ M) was used as inhibitor of nonspecific cholinesterases. The histochemistry was carried out on serial sagittal sections of portal vein transplants *in situ*. The isolated transplants used in the field stimulation experiments were subsequently pro-

Fig. 1 Spontaneous activity and responses to field stimulation and drug application in a strip of portal vein transplanted to the region of the hippocampus and the caudal diencephalon, 30 d survival. Atropine reduces the response to field stimulation and eliminates completely the effect of ACh. The remaining, atropine-resistant component of the electrical response and the excitatory action of NA are abolished by PBZ. We conclude that in this specimen both cholinergic and adrenergic central neurones have established functional connections with the smooth muscle.

cessed for fluorescence histochemistry of adrenergic nerves.

In its position in the caudal diencephalon and the hippocampus, the portal vein transplant was invaded by regenerating fibres from the locus coeruleus NA axons, running in the so-called dorsal tegmental bundle^{3,6,7} and by AChE-positive fibres (Fig. 2). The principal source of the AChE-positive fibres was from lesioned axons running in the alveus, cingulum and the supracallosal striae, belonging to the septo-hippocampal AChE-positive pathways¹² (Fig. 2c). There is now much evidence¹³⁻¹⁵ that this projection system is cholinergic. A contribution by peripheral AChE-positive parasympathetic fibres was only observed when the transplant reached all the way down to the interpeduncular fossa. In such transplants the parasympathetic fibres of the pial vessels¹⁶ were seen to have grown into the ventral part of the portal strip. In transplants that ended about 1.5 mm or more dorsal to the fossa no such ingrowth of peripheral cholinergic axons could be detected.

In vitro, the normal portal vein shows spontaneous rhythmic contractions with a frequency of about 1–3 min⁻¹ and a strength of about 500 dyne^{8,9}. Transmural stimulation elicits excitatory contractile responses that are blocked by PBZ and by previous sympathetic denervation^{9,17-19}. Exogenous NA and ACh are both excitatory on the myogenic activity of the portal vein, and these actions are totally blocked by α -adrenoreceptor blockers and atropine, respectively^{9,19}.

A total of 17 portal vein transplants were tested *in vitro* and of these 16 showed a good survival as judged by, first, their spontaneous myogenic activity, and, second, their contraction responses to NA and ACh administered to the bath. Some of the transplants had a regular, rhythmic spontaneous activity much resembling that of the intact portal vein (Fig. 1), but the contractions were weaker (about 20–110 dyne). The periods of activity were often more prolonged than normal, and occurred with a frequency of 0.5–2 min⁻¹. The remaining preparations had a more disordered spontaneous activity, without clear-cut periods of rest. Most of the specimens retained their spontaneous activity throughout the experiment (usually 2–2.5 h). Field stimulation at 6 to 10 Hz evoked excitatory contractile responses in 11 of the spontaneously active portal transplants. Optimally, the stimulation-induced contractions were of the same magnitude as those elicited by 10⁻⁶ M NA or ACh in the bath (Fig. 1).

PBZ was used as the first blocker in 8 of the 11 preparations. The response to field stimulation was abolished in two, was reduced in four and remained virtually unaffected in two muscles of this group. Atropine was given to four of the six muscles with PBZ-resistant responses and in all

these the effect of field stimulation was completely abolished (Fig. 1). Three muscles received atropine as the first blocker. The response to field stimulation was abolished in one and remained in two of these preparations; these atropine-resistant responses were eliminated after PBZ. The results thus show that all responses to field stimulation could be abolished by PBZ and atropine, individually or in combination, indicating functional innervation of the muscles by adrenergic and/or cholinergic fibres. It may be pointed out that PBZ and atropine had no effect on the spontaneous myogenic activity but abolished specifically the responses to NA (10⁻⁶ M) and ACh (10⁻⁶ M), respectively. The efficiency of the receptor blockade was always tested by application of NA and ACh in these concentrations.

The fluorescence microscopical analysis of the *in vitro* stimulated transplants showed a good correlation between the PBZ-sensitive contractile responses to field stimulation and the presence of NA-containing fibres in the transplant. In the transplants showing no, or only very weak, spontaneous activities there occurred areas of necrosis, bleeding, or scar formation, and they were often poorly reinnervated from the brain.

The combined histochemical and physiological data provide strong evidence for functional neuromuscular connections being formed by the regenerated central adrenergic

Fig. 2 Reinnervation of portal vein transplants by central adrenergic and AChE-positive fibres, 25–30 d survival. *a*, Regenerated central NA-containing fibres in the muscle layer of the portal vein transplant, as seen in a transverse section of the transplant *in situ* (Falck–Hillarp method; $\times 75$); *b*, regenerated central AChE-positive fibres in a squash preparation of the isolated transplant ($\times 75$); *c*, sagittal section through the transplant in its position in the hippocampus (Hi) and the dorsal diencephalon (Di). AChE-positive fibres are seen to grow into the transplant (TR) from the alveus (A) and the cingulum (C). SP denotes the splenium of the corpus callosum. Rostral is to the right ($\times 16$).

and cholinergic axonal terminal networks in the transplanted portal strips. It is well established^{9,19,20} that transmural stimulation of the type used in the present study selectively excites the nerves in the tissue, and, therefore that the contractile responses are neuronally mediated. The effects of the receptor blockers observed in this study are consistent with this view and support the conclusion that the responses registered in the portal CNS transplants were due to the release of NA and ACh from the regenerated central fibres, acting on the smooth muscle receptors.

The adrenergic reinnervation was primarily accomplished by the locus coeruleus neurones. The characteristics of the neurotransmission restituted by the central adrenergic fibres in the transplant were quite similar to those of the normal portal vein^{17,18} or those of the portal vein reinnervated by peripheral sympathetic fibres²¹. Moreover, the efficacy of the central reinnervation was high in terms of the magnitude of the postsynaptic responses to neural stimulation. In fact, in the successful specimens they were as large as those evoked by a high concentration of exogenous NA.

Although it was not possible to remove surgically the intracranial parasympathetic innervation—as was done with the sympathetic one—it seems clear that at least in the more dorsally situated transplants the cholinergic neuroeffector responses were exclusively, or almost exclusively, mediated by regenerated central fibres, originating primarily from lesioned axons of the septo-hippocampal pathways. Interestingly, such cholinergic responses (remaining after α -adrenoreceptor blockade and being abolished by atropine) have not been detected in the normal rat portal vein although muscarinic cholinergic receptors are present^{9,17,18}. It therefore seems possible that in its location in the brain normally non-innervated cholinergic receptors will become reinnervated by the regenerating central cholinergic neurones, giving rise to a heterologous innervation similar to that described after cholinergic reinnervation of the cat nictitating membrane²²⁻²⁴.

The very limited restoration of function in adult mammals after brain damage is often explained by an insufficient regenerative capacity of central neurones and by their inability to re-establish functional connections^{25,26}. An important implication of the current studies on the reinnervation of peripheral transplants in the CNS would be that—when given the same growth conditions as in the peripheral nervous system—at least some neurone systems in the mammalian CNS will show an entirely adequate regenerative capacity resulting in a restitution of normal neurotransmission in the denervated tissue.

Differentiation of opiate agonist and antagonist receptor binding by protein modifying reagents

OPIATE antagonists differ from opiates only by the replacement of the N-methyl substituent with an N-allyl, N-cyclopropylmethyl or related group. Antagonists can reverse the pharmacological effects of opiates and so are important in the treatment of opiate overdose. Drugs that combine agonist and antagonist activities have potential as relatively nonaddicting analgesics. Although their mutual pharmacological antagonism indicates that they act at the same binding site, pharmacological discrepancies have prompted speculation that agonist and antagonist binding sites are separate^{1,2}. Biochemical study of receptor binding³⁻¹⁶ has shown that although opiate agonists and antagonists compete for the same receptor^{3,4}, there are differences in the way they interact with them^{7,10}. Physiological concentrations of sodium enhance the binding of ³H-antagonists but reduce that of ³H-agonists. Sodium diminishes the ability of pure agonists to inhibit binding of ³H-naloxone to the receptor, but has little influence on inhibitory effects of pure antagonists and intermediate effects on those of combination agonist-antagonist drugs. The molecular basis for these differences, however, is unclear. As a first step in this direction we now report that binding of opiate receptors is much more sensitive to degradation by protein reagents which are known to modify sulphhydryl groups than is binding by opiate antagonists. This suggests that distinct binding sites exist for agonists and antagonists, although they may both be on the same receptor.

Brains, minus cerebella, from male Sprague-Dawley rats (180-220 g) were homogenised in standard buffer (50 mM Tris-HCl, pH 7.7 at 25°C) and centrifuged at 49,500g for 15 min; the pellets were resuspended in 100 volumes of standard buffer, incubated at 37°C for 30 min, recentrifuged and resuspended in 100 volumes of standard buffer. Incubation at 37°C increases opiate receptor binding about 80% (G.W.P. and S.H.S., in preparation). The homogenates were then treated with the appropriate reagent, washed by centrifugation at 49,500g for 15 min and assayed with 100 mM NaCl and the appropriate ³H-opiate at 25°C for 30 min in the presence and absence of 1 μ M levallorphan, unless otherwise stated. Samples were filtered and counted as before^{5,8}. All results are the mean of triplicate determinations and are expressed as specific opiate receptor binding, representing total binding minus binding in the presence of 1 μ M levallorphan.

Treatment of rat brain membrane preparations with iodoacetamide (20 mM) markedly reduced the specific receptor binding of the ³H-opiate agonists oxymorphone, levorphanol and dihydromorphone but not of the ³H-opiate antagonists naloxone and levallorphan (Table 1). To ensure that these effects were not due to interactions of iodoac-

Table 1 Effect of iodoacetamide on receptor binding of ^3H -opiate agonists and antagonists

Opiate	Stereospecific opiate binding (c.p.m.)		
	Control	Iodoacetamide Treated	% Change
Antagonists			
^3H -naloxone	1,040	1,092	+ 5
^3H -levallorphan	1,551	1,672	+ 8
Agonists			
^3H -oxymorphone	719	401	-44
^3H -levorphanol	1,288	827	-36
^3H -dihydromorphone	1,871	878	-53

Rat brains were homogenised in 20 volumes of standard Tris buffer and centrifuged at 50,000g for 15 min. The pellet was resuspended in 100 volumes of standard Tris buffer and equal volumes were incubated in the presence and absence of 20 mM iodoacetamide for 20 min at 25°C. The homogenates were then centrifuged as before, resuspended in their original volumes and assayed with either (+)-3-hydroxy-N-allylmorphinan or (-)-3-hydroxy-N-allylmorphinan (levallorphan) at 200 nM and the appropriate ^3H -opiate. Samples were filtered and counted as described in the text. The following concentrations of ^3H -opiates were used: 1.7 nM ^3H -naloxone; 2.8 nM ^3H -levallorphan; 3.7 nM ^3H -oxymorphone; 4 nM ^3H -levorphanol, and 0.7 nM ^3H -dihydromorphone.

tamide with ^3H -drugs themselves, the experiments were performed with membrane preparations presumably washed free of iodoacetamide. To explore the possibility that residual iodoacetamide might have reacted with the labelled ligands, thin-layer chromatograms in three solvent systems were prepared for all five ^3H -opiates after incubation with 100 mM iodoacetamide for 20 min at 25°C. Under these conditions there were no detectable changes in the relative fronts of any of the ^3H -drugs. Treatment with iodoacetamide did not alter the amount of radioactivity at the origin as would be expected for the products of an iodoacetamide-opiate reaction. Moreover, if the effects of iodoacetamide were due to reaction of the ^3H -opiates with residual reagent, an extra wash should have removed more iodoacetamide and lessened the inhibition of binding. Membranes subjected to a second centrifugation and resuspension showed no lessening of inhibition. Thus, the effects of iodoacetamide are irreversible and not due to chemical modification of the labelled ligands.

To examine the specificity and sensitivity of the differential degradation of agonist and antagonist binding, we compared the effects of various concentrations of iodoacetamide, mercuriacetate, iodoacetic acid, *p*-aminophenylmercuric acetate, *p*-chloromercuribenzoate and *N*-ethylmaleimide on opiate receptor binding of ^3H -naloxone and ^3H -dihydromorphone (Table 2). At 5 mM, iodoacetamide maximally inhibited binding of ^3H -dihydromorphone by about 90%; in other experiments 0.1 mM iodoacetamide lowered it by 25%. By contrast, binding of ^3H -naloxone showed little sensitivity to iodoacetamide between 5 mM and 100 mM. *N*-ethylmaleimide similarly discriminated between binding of ^3H -naloxone and ^3H -dihydromorphone. Concentrations of 0.1 mM to 3 mM *N*-ethylmaleimide maximally inhibited ^3H -dihydromorphone binding 90–100% and as little as 10 μM *N*-ethylmaleimide lowered it by 66%. Only a 30% decrease in ^3H -naloxone binding could be detected at 0.3 mM *N*-ethylmaleimide with 35% and 60% reductions in binding at 1 and 3 mM *N*-ethylmaleimide respectively. *p*-Chloromercuribenzoate also discriminated between agonist and antagonist binding. While 20 μM *p*-chloromercuribenzoate lowered ^3H -dihydromorphone binding by about 85%, it decreased that of ^3H -naloxone by only 45%. Differential effects on the binding of agonists and antagonists were also found for *p*-aminophenylmercuric acetate and mercuriacetate, although their effects were not as dramatic. There was a clear-cut separation of the effects of *p*-aminophenylmercuric acetate at 20 μM on binding of ^3H -naloxone and ^3H -dihydromorphone with a 75% decrease in ^3H -dihydro-

morphine binding and only a 45% decrease in ^3H -naloxone binding.

Unlike the other reagents, iodoacetic acid at 1–25 mM did not differentiate between agonists and antagonists, having little effect on the binding of either ^3H -dihydromorphine or ^3H -naloxone.

All the reagents which inhibit opiate receptor binding as described here are known to affect sulphhydryl groups, but can affect other amino acid residues^{17–23}, and so we investigated whether their action derives from an effect on sulphhydryl groups. Brain homogenates were incubated with 10 μM or 50 μM *p*-aminophenylmercuric acetate for 10 min at 25°C and centrifuged. The pellets were resuspended in the original volume of buffer, divided into aliquots and reacted with β -mercaptoethanol (10 mM and 20 mM for aliquots treated 10 μM and 50 μM *p*-aminophenylmercuric acetate, respectively) or water. Samples were again centrifuged and the pellets resuspended in their original volume of buffer and assayed with ^3H -dihydromorphine. The binding was abolished in samples treated only with 10 μM and 50 μM *p*-aminophenylmercuric acetate. In samples exposed to 10 and 20 mM β -mercaptoethanol after the *p*-aminophenylmercuric acetate (10 and 50 μM), however, there was only a 45% and 65% reduction in binding. The ability of a sulphhydryl-containing compound to reverse the lowering of opiate receptor binding suggests that *p*-aminophenylmercuric acetate decreases binding of ^3H -dihydromorphine by an action on sulphhydryl groups associated with the opiate receptor.

In preliminary studies to determine whether protein reagents modify the opiate binding site itself, we attempted to protect the binding site by preincubating with opiates before treatment with 10 μM iodoacetamide. The binding

Table 2 Effect of protein modifying reagents on receptor binding of ^3H -naloxone and ^3H -dihydromorphine

Reagent	^3H -Naloxone binding (% control)	^3H -Dihydromorphine binding (% control)

Rat brains were homogenised and prepared as described in the text. All reagents were dissolved in water immediately before use except for *p*-aminophenylmercuric acetate, mercuriacetate and *p*-chloromercuribenzoate, which were dissolved in dimethylsulphoxide. Dimethylsulphoxide in the concentrations used has no effect on binding. ^3H -naloxone was present at 1 nM and ^3H -dihydromorphine at 0.6 nM. All binding assays were performed in the presence of 100 mM NaCl. All experiments were replicated at least twice. Each value is the mean of triplicate determinations which varied less than 8%.

site for ^3H -dihydromorphine can be protected from the influence of iodoacetamide by preincubation with naloxone, oxymorphone, morphine and nalorphine at $0.2\ \mu\text{M}$ (our work in preparation).

Our findings thus demonstrate chemical differences in binding sites on the opiate receptor for agonists and antagonists. Sulphydryl groups seem to be important components for differentiating the interactions of opiate agonists and antagonists with the opiate receptor.

Requirements for bursting pacemaker potential activity in molluscan neurones

THE mechanisms underlying endogenous rhythmical electrical activity of some molluscan neurones are not completely understood. Their membranes have several significant properties: (1) rapidly inactivating Na^+ and Ca^{2+} conductances associated with spikes¹⁻³; (2) voltage-dependent K^+ conductances (G_K) (delayed^{1,6} and anomalous rectification^{3,7}); and (3) a negative slope region (NSR) in the steady-state, voltage clamp current-voltage (I - V) curve^{8,9}. Although (1) is unnecessary for bursting pacemaker potentials (BPPs)⁴ the relationship of (2) and (3) to the generation of BPPs has not been elucidated completely. We present here evidence that the NSR of the I - V curve is due to a voltage-dependent Na^+ conductance (G_{Na}) which inactivates incompletely and that BPPs depend on this conductance coupled to cyclical changes in G_K .

In a typical experiment fused ganglia were isolated from the land snail (*Otala lactea*) or the sea hare (*Aplysia californica*), fixed in a chamber and perfused with saline (in mM, for *Aplysia*: 500 NaCl, 10 KCl, 50 MgCl_2 , 10 CaCl_2 ,

and 10 Tris-Cl, pH 7.8; for *Otala*: 100 NaCl, 4 KCl, 10 CaCl_2 , 5 MgCl_2 , 5 Tris-Cl, pH 7.8) at 20-21° C. Cell 11 of *Otala*⁵ or R15 of *Aplysia*² which normally generate BPPs were penetrated with two microelectrodes (3 M KCl or 7.5 M CsCl). Conventional methods were used to record the cell's electrical activity and voltage clamp its membrane potential. One microelectrode monitored V_m while the other carried current. The settling time of the system was about 1 ms for voltage steps up to 50 mV. Clamping current was measured by an operational amplifier that held the bath at ground.

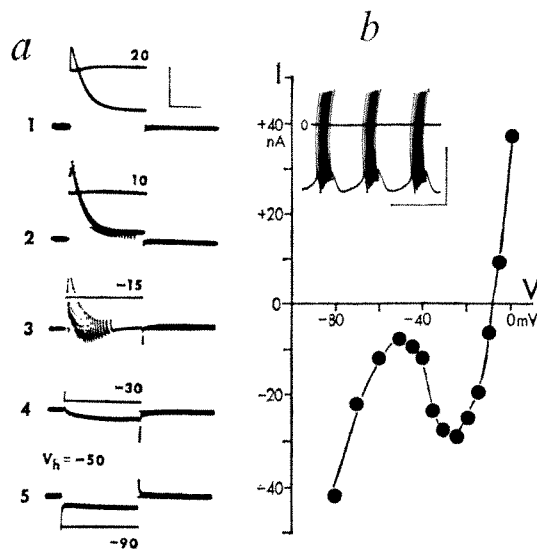

Fig. 1 Data from cell R15 of *Aplysia californica*. *a*, From voltage clamp. Voltage (thin lines) and current (thick lines) traces for 5-s pulse commands from holding potential (V_{holding} , V_h) of -50 mV to potentials indicated by numbers adjacent to voltage trace. Traces begin with voltage and current traces superimposed. Positive-going potentials and (outward) currents are displayed upward. Calibration: 45 mV for voltage traces, 500 nA (trace 1), 200 nA (trace 2), 100 nA (trace 3) and 50 nA (traces 4 and 5) for current traces; 2.5 s. See text for details. *b*, I - V curve from voltage clamp data shown in (*a*) (see text for details). Inset shows spontaneous BPP oscillations in the unclamped cell. Calibrations 50 mV, 25 s. In this and subsequent figures zero membrane potential is indicated by a horizontal line marked 0.

The steady-state current recorded from cells generating BPPs under voltage clamp are always inward (I_m) between -60 and -30 mV, the normal BPP range^{8,9}. The membrane was clamped between -60 and -30 mV to a potential which required the least holding I_m . Voltage step commands were applied (4-5 s) and the currents required to clamp the membrane at various potentials recorded. Four currents were identified: (1) an inward somatic spike current (not shown due to the slow time base); (2) a slowly decaying outward K^+ current (delayed rectification) for large depolarising steps (Fig. 1*a*, traces 1-3), (3) a voltage-dependent increase in I_m for steps between -45 and -30 mV, (trace 4) and (4) a time-dependent increase in inward current during large hyperpolarising commands (anomalous rectification) (trace 5). There were also rapid biphasic currents (traces 2 and 3) representing spikes in unclamped portions of the cell's axon.

I - V curves were constructed by measuring the minimum, slow changing current (least positive or most negative) during each voltage step at times greater than 1 s after the change in V_m and plotting this plus the holding current against the command voltage (Fig. 1*b*). Inward spike currents were excluded. Sometimes the slowly changing current was partially obscured by axon spike currents (for example, trace 3, where the minimum current was estimated at 2 s during the command step). The I - V curves were N-shaped (Fig. 1*b*) and the net, quasi-steady state current of cells generating BPPs rarely, if ever, became outward at

a V_m more negative than -30 mV. Qualitatively similar I - V curves were obtained in all cells generating BPPs. I_{in} from cell 11 was small but could be increased by replacing $[Ca^{2+}]_o$ and by iontophoresing Cs^+ ions intracellularly. This allowed quantitative analysis of the I_{in} and NSR.

The ionic mechanisms underlying the voltage-dependent I_{in} were assessed by stepwise replacement of most of Na^+ with equimolar amounts of $Tris^+$, Li^+ or sucrose. Reductions of $[Na^+]_o$ decreased the size of the I_{in} evoked at a given V_m (-30 mV in Fig. 2b) and of the NSR (Fig. 2c). All substitutions for $[Na^+]_o$ gave similar results (Fig. 2d): I_{in} at a given V_m varied linearly with $[Na^+]_o$. Reducing either the $[Cl^-]_o$ with SO_4^{2-} or methane sulphonate anions or the $[K^+]_o$ did not alter the I_{in} . These results suggest that the increased I_{in} evoked over the -50 to -30 mV V_m range is a Na current (I_{Na}) due primarily to a voltage-dependent Na^+ conductance (G_{Na}). This G_{Na} activates rapidly with depolarisation since the I_{in} develops quickly. The early decline in the I_{in} may represent some inactivation of G_{Na} but the persistence of I_{in} for the duration of a 5 s pulse indicates that G_{Na} does not inactivate completely. On returning V_m to the holding V_m , the inward tail currents relax within seconds, suggesting that G_{Na} inactivates quickly with hyperpolarisation.

The I - V properties of this persistent G_{Na} were evaluated

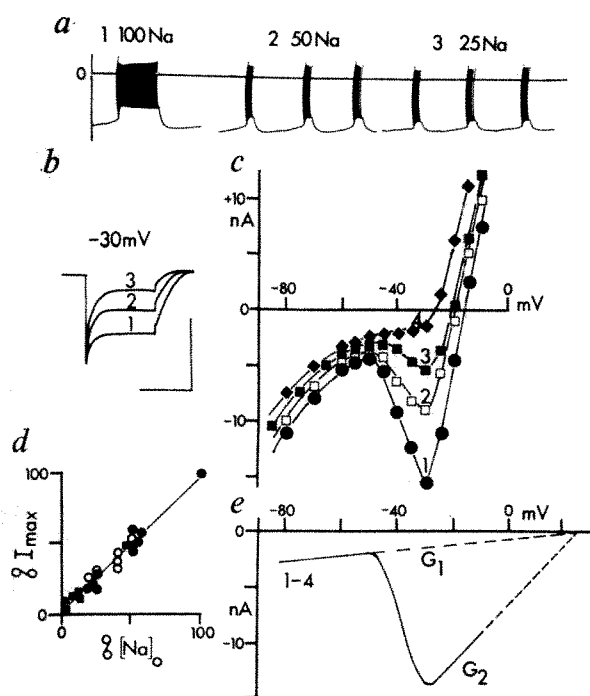

Fig. 2 Effects of altering $[Na^+]_o$ on membrane properties of BPP neurones. Data in (a-c) and (e) from cell 11 of *Otala lactea*. d contains data from both cell 11 and cell R15. Cs^+ ions were iontophoresed intracellularly by means of a microelectrode in cell 11 before measurements. In (a-c) data labelled 1 (or \bullet), 2 (or \square) and 3 (or \blacksquare) were obtained when the $[Na^+]_o$ was, respectively, 100, 50 and 25 mM (Na^+ replaced with $Tris^+$). Other extracellular ions were kept constant (10 mM $SrCl_2$, 4 mM KCl). a, Effect of reducing $[Na^+]_o$ on the BPP; b, line traces of voltage clamp currents recorded in pulsing the membrane from holding of -50 mV to -30 mV for 5 s in different $[Na^+]_o$ s; c, plots of voltage-clamp I - V curves. The curve linked by diamonds was taken in 25 mM $NaCl$, 80 mM $SrCl_2$, 4 mM KCl and 5 mM $Tris-Cl$. V_h always -50 mV; d, the clamp current, at -30 mV, as a percentage of current required to clamp the membrane at -30 mV in maximum $[Na^+]_o$ against the percentage of the maximum $[Na^+]_o$. $[Na^+]_o$ replacements were Li^+ (\blacksquare), $Tris^+$ (\bullet) and sucrose (\circ). e, Curve \bullet minus curve Δ of (c), see text. The solid parts of the curve are from the data in (c). The dashed lines are straight-line extrapolations, see text. Calibrations: 90 mV, 25 s (a); 12.5 nA, 4 s (b).

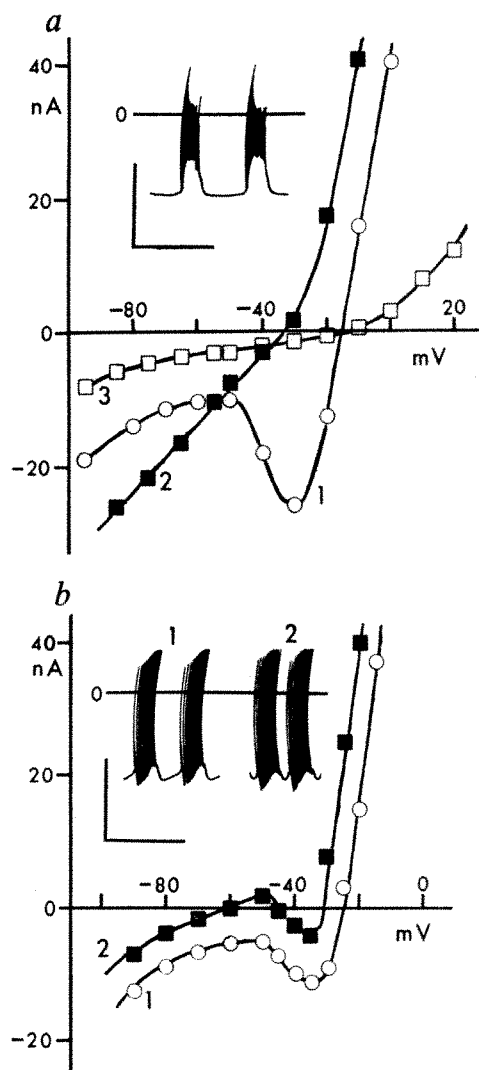

Fig. 3 Effects of extracellular ionic alteration on BPP activity and on membrane properties in cell 11 of *Otala lactea*. In all experiments extracellular $NaCl$ (100 mM) and $Tris-Cl$ (5 mM) were held constant. a, I - V (\circ) the medium also contained 10 mM $SrCl_2$ and 4 mM KCl and the cell had been injected with Cs^+ . Inset: BPPs under such conditions. \blacksquare , KCl was replaced with 8 mM $CsCl$; \square , the cell was returned to 4 mM KCl and the $SrCl_2$ replaced with 10 mM $CoCl_2$; V_h for all curves in a = -50 mV. b, For \circ the medium contained 10 mM $CaCl_2$ and 4 mM KCl , $V_h = -50$ mV. Inset 1: spontaneous BPP activity; \blacksquare the KCl was reduced to 1 mM and 5 mM $MgCl_2$ was added to the medium. The cell was silent at -60 mV but BPP activity could be elicited by injecting a steady 5 nA depolarising current through an intracellular microelectrode (inset 2). Calibration: 50 mV, 25 s.

by subtracting the I - V curve obtained when the persistent I_{Na} was assumed to be zero from that under control conditions (Fig. 2c, curve 1). The former conditions existed in a solution containing 25 mM $[Na^+]_o$ and 80 mM $[Sr^{2+}]_o$ which abolished the NSR of the curve without changing other measured currents (Fig. 2c, curve 4). The subtraction yields a curve (Fig. 2e) that indicates this persistent G_{Na} has voltage-independent and voltage-dependent components, which extrapolate to a reversal potential of about $+25$ mV, near the peak of the Na-dependent spike of this cell (Fig. 2a, part 1). These data suggest that the persistent I_{in} required to clamp the membrane at potentials in the NSR of the I - V curve is carried by Na^+ ions and that the NSR of the steady-state I - V curve is mainly due to a voltage-dependent, incompletely or non-inactivating G_{Na} . This persistent G_{Na} differs from the G_{Na} associated with spikes: (1) its thresh-

hold for activation is more negative (Fig. 1a); (2) inactivation is incomplete or absent (Figs 1a and 2b); (3) tetrodotoxin-sensitivity is absent⁴; (4) Li^+ cannot substitute for Na^+ in otherwise normal saline and (5) it is very temperature sensitive⁴.

Our data also indicate that the amplitude of the BPP (the difference between the trough and crest of a BPP) correlated with the magnitude of the persistent I_{Na} (Fig. 2a and d). Qualitative changes in these two variables (BPP, I_{Na}) resulted from other ionic manipulations: both were abolished by replacing $[\text{K}^+]_0$ with $[\text{Cs}^+]_0$ which markedly increased membrane conductance (Fig. 3a). When unclamped, the cell depolarised, fired repetitively and would not generate BPPs with hyperpolarising current (not shown). Both variables were also lost by replacing $[\text{Sr}^{2+}]_0$ with $[\text{Co}^{2+}]_0$ (Fig. 3a); again, BPP activity was not restored by extrinsic current. Others have shown correlations between the NSR and BPP activity when they were altered by temperature changes⁸ and pharmacologically⁹. While these data suggest that a persistent, voltage-dependent G_{Na} is required for BPP activity, it is not sufficient. Application of sufficient hyperpolarising or depolarising current can prevent BPPs^{3,4}, leading either to silence or repetitive firing. V_m behaviour changed similarly when the bathing solution was altered. When MgCl_2 was added and KCl was reduced the cell hyperpolarised to -60 mV and became silent; however, injection of a steady depolarisation current restored BPPs (Fig. 3b, inset 2). Conversely, after excessive Cs^+ injections, the cell shown in Fig. 3a depolarised to -15 mV and generated BPPs only with steady hyperpolarising current (Fig. 3a, inset). Under voltage clamp, both cells had a persistent G_{Na} and the V-axis intersected the I - V curves near the resting V_m of the unclamped membrane (-60 mV and -15 mV, respectively) (Fig. 3b, curve 2 and Fig. 3a, curve 1). Thus, these procedures resulted in a stable potential on a positive slope of the I - V curve and zero current was required to clamp V_m . Cells with spontaneous BPPs did not have a resting potential; the intersection

of the V-axis with their I - V curves was therefore, not a stable potential.

Another proposed requirement for BPP activity is a G_{K} with appropriate voltage- and time-dependencies^{3,12,13}. To study this contribution, V_m was clamped to -50 mV at different times during the BPP cycle and the resulting currents recorded (Fig. 4b, traces 1-4). (The record in Fig. 4a was not taken when the cell was clamped, but only indicates the times during the cycle when V_m was clamped.) The tail current following return of V_m to -50 mV from a 5 s command to -15 mV is also shown (Fig. 4b, trace 5). This tail current is most likely due to a G_{K} (refs 1, 6) for times longer than 5 s all currents decay exponentially with a time constant of about 16 s. If these are K^+ currents, the zero time intercepts of the curves in Fig. 4c (traces 1-4) reflect G_{K} at the onset of the clamp (values listed under $I_{\text{K}}(0)$ in Fig. 4b). G_{K} is minimal at the beginning of the bursting phase of the BPP (time 1), increases during the bursting period (times 2 and 3), becomes maximal at its end and decreases with time as the V_m slowly depolarises (times 4 to 1), as previously suggested^{3,12,13}.

In summary, two membrane properties are associated with BPP activity: (1) a G_{Na} with voltage-independent and voltage-dependent components which inactivates incompletely; (2) a voltage-dependent G_{K} with slow kinetics in the BPP range of V_m . Additional prerequisites include adequate membrane resistance and the absence of a steady-state electromotive force.

A possible mechanism of the interaction of these properties in producing spontaneous BPP activity is as follows. Let the V_m begin at its most hyperpolarised point; the slow decline in the voltage-dependent G_{K} which brought V_m to this point, along with the voltage-independent component of the persistent G_{Na} , depolarises V_m . When V_m reaches threshold for the voltage-dependent component of the persistent G_{Na} , it activates quickly and V_m depolarises rapidly. V_m remains depolarised from lack of inactivation of G_{Na} . This allows a burst of spikes and activates the voltage-dependent G_{K} which eventually generates sufficient hyperpolarising force to lead to the post-burst hyperpolarisation of V_m . This hyperpolarisation occurs rapidly since the voltage-dependent component of G_{Na} turns off quickly, and another BPP cycle begins. This description thus extends the hypothesis that pacemaker activity is due to a high resting G_{Na} and the cycling G_{K} . It also indicates the importance of the NSR in the I - V curve since this region is due to the voltage-dependent G_{Na} which inactivates incompletely.

Fig. 4 Currents recorded by voltage clamping at different phases of the spontaneous BPP cycle. a, Arrows indicate times during the BPP cycle when the cell was clamped to -50 mV; b, traces 1-4 are line drawings of the currents recorded at the times numbered in (a). Zero current indicated by the horizontal lines below the numbers in each trace. Trace 5: the tail current recorded when the cell was returned to V_h (-50 mV) from a 5-s step to -15 mV; c, semilog plot of current time for currents shown in (b). The slowly declining currents all fit an exponential with a time-constant of decay (τ) of about 16 s. Zero time was the onset of the clamp for 1-4 and the beginning of the tail-current in 5. Zero-time intercepts of each of these curves are listed under $I_{\text{K}}(0)$ in (b). Calibration: 60 mV, 30 s in (a); 60 nA, 30 s in (b).

Selection for diploid cells in suspension cultures of *Haplopappus gracilis*

CHANGES in the number and structure of chromosomes of plant cells cultured *in vitro* are of common occurrence¹, and cell populations devoid of diploid karyotype have been reported²⁻⁴. The chromosome number is known to become variable even in clones derived from single cells^{5,6}. In the case of *Picea glauca* Voss. ($n = 21$) callus cultures, a positive correlation between growth rate and chromosome number was observed⁷, which indicates a selection for polyploid cells. Only diploid cells were, however, observed in mitosis in suspension cultures of *Haplopappus gracilis* (Nutt.) Gray ($n = 2$) (ref. 2), *Medicago sativa* L. ($n = 16$) (ref. 8) and *Crepis capillaris* L. Wallr. ($n = 3$) (ref. 9). This could result from polyploid cells dividing less frequently than diploid cells, as diploid and polyploid cells differ physiologically. A strong selection for diploid cells was observed¹⁰ in *Vicia hajastana* Grossh. ($n = 5$) suspension cultures initiated from mature seeds. It therefore seemed likely that cell cultures of other plant species with a low chromosome number, $n = 7$ or less, would show a selection for diploid cells.

Callus cultures were initiated from hypocotyl segments of 3-d-old seedlings of *H. gracilis* on agar B5 medium¹¹ containing 4.5×10^{-6} M 2,4-dichlorophenoxyacetic acid (2,4-D). The calli were kept in a culture room at constant temperature (27–28°C) and light (2,000 lx). Subculturing was carried out every 3 weeks. After 122 d in culture, some cells were transferred to liquid B5 medium with 2,4-D at the same concentration. The suspension cultures were subcultured every 3 d, and were agitated by a gyratory shaker at 150 r.p.m. The cytological technique was essentially that of Singh *et al.*¹⁰.

An increase in the frequency of aneuploid cells was observed after 94 d in culture; a drastic decrease subsequently occurred. The frequency of diploid cells increased consistently whereas that of tetraploid cells steadily declined (Table 1). Anaphase analyses revealed a number of anomalies, such as bridges, fragments, unequal distribution of chromatids and laggards in low frequencies (1–3%). Chromosomes with altered mor-

phology were also observed at metaphase. These anomalies could have been induced by 2,4-D, or some other factor, present in the culture medium, and would lead to the production of aneuploid cells from diploid and polyploid cells. Furthermore, endoreduplication is likely to occur in plant cells cultured *in vitro*^{12,13}. The increase in the frequency of diploid cells under such a condition, therefore, clearly shows a strong selection for such cells. A similar selection for diploid cells was observed in suspension cultures of *H. ravenii* ($n = 4$), a closely related species, initiated from stem segments¹⁴.

The cytogenetic behaviour of *H. gracilis* cells has been investigated previously^{2,15-18}. In some studies, a systematic analysis of the changes in the frequencies of various karyotypes during the *in vitro* culture was not made^{2,16,17}, but where such an analysis was made^{15,18}, an increase in the frequency of polyploid cells was observed. Since agar media were used^{15,18}, these findings do not necessarily contradict the results reported here. An increase in the frequency of polyploid cells was observed when *H. gracilis* cells were cultured on agar B5 medium¹⁹. Only diploid cells were observed in a suspension culture of *H. gracilis*, which was interpreted to indicate a selection for diploid cells².

The distribution of the two chromosomes of *H. gracilis* in the aneuploid cells was non-random; chromosome I was present more often than expected. In fact, almost all of the cells with five chromosomes had an extra chromosome I. A similar non-random distribution of chromosomes has been observed in suspension cultures of *V. hajastana*¹⁰. Since both chromosome I and II seem to be equally susceptible to mitotic irregularities, it seems that cells possessing an extra chromosome I were at a selective advantage over those possessing an extra chromosome II.

The present study was carried out at Crop Science Department, University of Saskatchewan, Saskatoon, Canada, and was supported by the National Research Council of Canada. We thank Dr R. Tanaka, Hiroshima, for a gift of *H. gracilis* seeds.

Lack of permeability of mouse placenta to maternal and foetal cells

IN man, foetal leukocytes circulate in the maternal blood in most pregnancies and are occasionally detected up to 1 yr after delivery¹⁻³. On the other hand, maternal white blood corpuscles have seldom been found in the foetal

circulation⁶⁻⁸. The reason for this paradoxical persistence of potentially histoincompatible cells in the mother's circulation is unknown. The fact that paternally-derived foetal HL-A antigens are difficult to demonstrate in cord blood samples⁹ suggests that the factors determining incompatibility in the foetal cells are either masked by blocking antibodies or are not expressed¹⁰.

In the mouse, information exists only on the passage of blood cells from mother to foetus¹¹⁻¹⁶. Both radioactive labelling¹¹⁻¹⁵, and cytogenetic markers^{12-14,16}, have been used to differentiate between foetal and maternal cells. The data are, however, inconsistent¹¹⁻¹⁶, probably resulting from the pitfalls of the methods used.

To overcome methodological difficulties, pregnancies resulting from laboratory mouse \times tobacco mouse matings were studied. The laboratory mouse has 40 acrocentric chromosomes, whereas the tobacco mouse has only 26 chromosomes, 14 of which are metacentric¹⁷. Since the hybrid has 33 chromosomes¹⁸, seven of which are metacentric, a mitosis from a foetus of such a cross can be distinguished without difficulty from a parental mitosis.

The passage of lymphocytes from foetus to mother was studied in phytohaemagglutinin (PHA) or leucoagglutinin (LA) cultures of blood from female laboratory mice mated with male tobacco mice. Blood samples were taken between the second and third weeks of pregnancy (in ten instances), or immediately after delivery (in five instances), and cultured as described¹⁹. Chromosome preparations were made by conventional methods²⁰ and stained with Giemsa; 100-1,000 mitoses were studied from each animal.

Transmission of blood cells in the opposite direction, from mother to foetus, was studied in identical matings. Ten newborn mice (two from each of five litters) were killed and chromosome preparations made from liver, spleen, bone marrow and thymus¹², and stained with Giemsa. A total of 10,000 mitotic cells was studied.

Table 1 Mitotic studies on cultures of lymphocytes from female laboratory mice mated with male tobacco mice

	No. of animals	No. of cells	No. of foetal cells
During pregnancy	10	4,995	0
After delivery	5	4,096	0
Total	15	9,091	0

PHA or LA cultures were carried out between weeks 2 and 3 of pregnancy in ten animals, and immediately after delivery in five animals.

The results of chromosome studies on maternal lymphocyte cultures are presented in Table 1. Foetal mitoses were never found in these cultures; neither was there any evidence of transmission of blood cells from mother to foetus.

The results of Tuffrey *et al.*^{12,13}, however, indicate transmission of maternal cells into the foetus. These workers used the T₆ chromosome marker in a syngeneic system to distinguish foetal mitoses from maternal mitoses and found maternal cells in up to 33% of mice which had developed in the uterus of foster mothers after transplantation at the blastocyst stage. Later, using the same marker, they found maternal cells in the offspring after normal pregnancies. Others^{14,16} using the T₆ marker, have been unable to confirm these data, and suggest that differences between mouse strains or misinterpretation of the T₆ chromosome are possible reasons for these discrepancies. The main limitation of these studies is that only mitoses, and not interphase cells, have been studied. Negative results might be due to inability of foetal and maternal cells crossing the mouse placenta to enter mitotic division in such experiments. We have also examined mitotic cells.

Radioactive labelling has been used to mark maternal blood cells in the circulation of the offspring^{11,15}. One group¹¹ was able to demonstrate transplacental passage of red blood corpuscles in a few pregnancies, and the other¹⁵

Fig. 1 *a*, Cultured lymphocyte of a laboratory mouse in mitosis. The cell has 40 acrocentric chromosomes. *b*, A mitosis from a chromosome preparation of liver from a laboratory mouse \times tobacco mouse hybrid. The cell has 33 chromosomes, seven of which are metacentric.

found maternal erythrocytes and leukocytes in the blood of most foetuses. The method is open to question, however, as passage of free isotope molecules across the placenta and uptake of these by foetal cells cannot be excluded.

The human placenta seems to be permeable to blood cells, and foreign cells invade the circulation of both the foetus and the mother often without causing any clinical symptoms²⁻⁸ and so it may seem surprising that this is not so in the mouse. Reasons may be that the placental structure of the two species differ; differences in the number of foetuses, time of gestation or in the validity of the methods used to study the phenomenon may also be responsible. In man, the methods seem to be adequate and the results convincing, but in the mouse suitable markers are lacking. One limitation is the lack of markers for mitotic studies, the other the failure to devise a method for distinguishing between foetal and maternal cells during interphase. We have overcome the first problem but not the second. We have not found any evidence for the transplacental passage of blood cells in the mouse, but the results must be regarded with caution until markers are found by which foetal and maternal cells can be distinguished from each other at interphase.

Supported by grants from the Finnish National Research Council for Natural and Medical Sciences. We thank Professor Alfred Gropp for the tobacco mice, and for advice in their breeding, and Professor Albert de la Chapelle for his help.

Cytochalasin B, the blood platelet release reaction and cyclic GMP

CYTOCHALASIN B (CB) affects a wide range of cellular processes that appear to be contractile in nature¹. The molecular mechanisms responsible for these effects are uncertain, though it is known that CB interferes with microfilament function¹ and can block transport of glucose across cell membranes^{2,3}. Secretion by exocytosis has been shown to be inhibited by CB in some cell types⁴⁻⁸ but to be potentiated by CB in others⁹⁻¹². We describe here the effects of CB on the release reaction of blood platelets induced by collagen fibres, a process in which the contents of both amine storage granules (5-HT, ADP, ATP) and lysosomes are secreted¹³ and which leads to platelet aggregation mediated by the ADP released¹⁴. Although previous studies have shown that CB inhibits various platelet activities including clot retraction¹⁵⁻¹⁷ and platelet aggregation^{16,17}, we now find that lower concentrations of CB markedly potentiate both the secretory activities of the platelet and release-dependent aggregation. Because collagen-induced platelet aggregation is associated with an increase in intracellular cyclic GMP¹⁸, a compound which potentiates secretion by some cells^{19,20}, and

because it has been suggested that CB may stimulate leukotaxis²¹ by increasing cyclic GMP²¹, we have studied the relationship between the platelet release reaction and platelet cyclic GMP levels in the presence and absence of CB. The results show that CB does not potentiate the release reaction through any direct effect on cyclic GMP levels.

Experiments were performed either with human heparinised platelet-rich plasma (PRP) adjusted to contain 470,000 platelets μl^{-1} (ref. 22) or with a suspension of washed human platelets ($560,000 \mu\text{l}^{-1}$) suspended in Tyrode's solution containing 0.35% bovine serum albumin and apyrase²³. Platelet 5-HT was labelled by preincubating PRP with $1 \mu\text{M}$ ^{14}C -5-HT (ref. 22) for 1 h or washed platelets with $2 \mu\text{M}$ ^{14}C -5-HT for 20 min during the first wash. Samples (0.85 ml) of labelled PRP or washed platelet suspension were mixed with $2 \mu\text{l}$ dimethyl sulphoxide \pm CB and $48-128 \mu\text{l}$ 0.154 M NaCl and were incubated at 37°C for 10 min before addition of further 0.154 M NaCl \pm collagen to give a final volume of 1 ml. Samples were transferred to an apparatus for the turbidometric measurement of platelet aggregation (Payton Associates Ltd., Scarborough, Ontario) 0.5 min or 1 min before the last addition and then stirred continuously. Incubations were usually terminated by addition of 0.1 ml 0.077 M Na_3EDTA and centrifugation for 0.5 min at $12,000g$ (Eppendorf 3200). ^{14}C and enzyme activities were measured in the supernatants and in a corresponding volume of PRP or washed platelet suspension in which the platelets were lysed (see Table 1 for methods). Values in the supernatant from a control without CB or collagen were subtracted and the percentage release of platelet constituents calculated. CB did not affect the activities of the enzymes assayed. Bovine collagen (Sigma) was prepared for use by homogenisation in 0.154 M NaCl at 0°C (Polytron homogeniser); coarse fibres were removed by centrifugation ($100g$, 5 min). The collagen remaining in suspension was determined gravimetrically after high speed centrifugation, washing with water and drying at 110°C .

Preliminary experiments established that 0.2% dimethyl sulphoxide (the solvent for CB) did not affect the release reaction and that CB did not affect the uptake of ^{14}C -5-HT by platelets. Addition of CB without collagen did not cause

Table 1 Effects of CB on the release of platelet constituents induced by collagen fibres

Experiment 1	Additions		^{14}C -5-HT	Release of platelet constituents (%)			Lactate dehydrogenase

PRP was used in experiment 1 and washed platelets in experiment 2. Final concentrations of collagen and CB are given. Incubations were terminated 3 min after addition of collagen. ^{14}C was counted by liquid scintillation¹⁸. β -Glucuronidase and β -N-acetylglucosaminidase were assayed at 30°C in 50 mM citrate buffer, pH 4.5, containing 0.25% Triton X-100 and 4 mM *p*-nitrophenyl- β -D-glucuronide or *p*-nitrophenyl-N-acetyl- β -D-glucosaminide respectively. After 20 h or 2 h respectively these reactions were stopped with 9 volumes 0.02 N NaOH and the *p*-nitrophenol liberated was measured spectrophotometrically at 405 nm. Lactate dehydrogenase was assayed at 30°C in the presence of 0.1% Triton X-100 using a standard method²⁴.

Table 2 Effects of CB on the platelet ^3H -cyclic GMP levels observed in the presence of weak and strong release stimuli

Additions	Release of ^{14}C -5-HT (%)	^3H -Cyclic GMP d.p.m. per sample	2P
—	—	$1,297 \pm 105$	—
CB	<1	$1,436 \pm 44$	>0.2
Collagen (2 $\mu\text{g ml}^{-1}$)	1	$2,222 \pm 357$	—
Collagen (2 $\mu\text{g ml}^{-1}$) + CB	23	$4,761 \pm 465$	<0.02, >0.01
Collagen (14 $\mu\text{g ml}^{-1}$)	48	$4,214 \pm 160$	—
Collagen (14 $\mu\text{g ml}^{-1}$) + CB	62	$4,230 \pm 296$	>0.95
Collagen (136 $\mu\text{g ml}^{-1}$)	76	$5,519 \pm 786$	—
Collagen (136 $\mu\text{g ml}^{-1}$) + CB	78	$6,844 \pm 778$	>0.2
ADP (2 μM)	2	$4,555 \pm 261$	—
ADP (2 μM) + CB	1	$4,919 \pm 159$	>0.2

The final CB concentration was $5 \mu\text{g ml}^{-1}$ when present. Incubations were terminated 2 min after addition of the release stimulus (final concentration given). ^3H -Cyclic GMP values are means \pm s.e.m. from three identically treated samples of PRP. The significance of the effects of CB was determined by unpaired Student's *t* tests.

aggregation or induce the release of platelet constituents. But addition of $1\text{--}20 \mu\text{g CB ml}^{-1}$ to PRP before a threshold amount of collagen markedly increased the extent of platelet aggregation (Fig. 1). This was associated with a several-fold increase in release of ^{14}C -5-HT, suggesting that the enhanced aggregation was mediated by ADP released with the 5-HT. An almost identical potentiation of ^{14}C -5-HT release was observed whether CB was added with the collagen or up to 50 min before. The greatest increase in release was with $10 \mu\text{g CB ml}^{-1}$ in PRP (Fig. 1; Table 1, experiment 1). Despite these effects, CB delayed platelet aggregation and at concentrations greater than $20 \mu\text{g ml}^{-1}$ suppressed the change in platelet shape (upward deflection of

the recording) that normally precedes aggregation (Fig. 1). Higher CB concentrations ($> 40 \mu\text{g ml}^{-1}$) also delayed and inhibited the release reaction. With amounts of collagen that induced complete platelet aggregation only the inhibitory effects of CB on aggregation were seen in turbidometric recordings, even when release of ^{14}C -5-HT was potentiated. Collagen, particularly at high concentrations, also induced the release of the lysosomal enzymes, β -glucuronidase and β -N-acetylglucosaminidase, from platelets in PRP. In the presence of $10 \mu\text{g CB ml}^{-1}$ the amounts released were approximately doubled (Table 1). In no experiment were more than trace amounts of lactate dehydrogenase released, indicating that CB specifically potentiated the release reaction rather than causing a generalised leakage of cell constituents. Very similar results were obtained with washed platelets (Table 1, experiment 2), but the concentration of CB required for maximum potentiation of the release reaction was much lower ($0.1 \mu\text{g ml}^{-1}$). Above $1 \mu\text{g ml}^{-1}$, CB almost completely suppressed both the release of washed platelet constituents and aggregation.

Our finding that low concentrations of CB can potentiate the platelet release reaction suggests that under appropriate conditions other secretory processes reported to be inhibited by CB^{4-8} may be similarly potentiated. In two instances there is already evidence for this^{25,26}. The question arises whether the potentiation and inhibition of the release reaction by CB involve different mechanisms of action at the molecular level. Lin *et al.*²⁷ have reported that bovine platelets have high and low affinity binding sites for CB and that serum reduces binding to both. The dissociation constants of CB at these two classes of binding site in the presence and absence of serum correlate moderately well with the respective concentrations we required for potentiation or inhibition of the release reaction in the human PRP and washed platelet systems. Lin *et al.*²⁷ suggest that their high affinity sites may be associated with hexose transport and the low affinity sites with cellular contractility. Although CB does block glucose metabolism in platelets¹⁷, it seemed unlikely that this could potentiate the release reaction. We therefore investigated the possibility that cyclic GMP might mediate this action of CB.

To permit measurement of changes in platelet cyclic GMP by a prelabelling method¹⁸, $2 \mu\text{M } ^3\text{H}$ -guanine (4 Ci mmol^{-1}) was included with ^{14}C -5-HT in the preincubation step in some experiments with PRP. ^3H -Cyclic GMP was then isolated from incubations stopped by addition of $0.2 \text{ ml } 3 \text{ N HClO}_4$ with unlabelled cyclic GMP¹⁸. Collagen caused a concentration-dependent increase in platelet ^3H -cyclic GMP up to about four times the basal level (Table 2). The ^3H -cyclic GMP level increased rapidly after a short interval at approximately the same time as the most rapid release of ^{14}C -5-HT (Fig. 2). As release could not be measured instantaneously, we could not determine whether or not the increase in ^3H -cyclic GMP preceded the release reaction. After the initial rapid increase, the ^3H -cyclic GMP concentration rose more slowly for at least 3 min, despite cessation of release and some reuptake of

Fig. 1 Effects of CB on platelet aggregation and release of ^{14}C -5-HT induced by collagen. The amount of collagen added (final concentration $2 \mu\text{g ml}^{-1}$) was adjusted so as to cause only slight platelet aggregation in the absence of CB. Incubations were terminated 3 min after addition of collagen. Release of ^{14}C -5-HT (%) at this time is indicated in parentheses. Final CB concentrations ($\mu\text{g ml}^{-1}$) were: a, 0; b, 2; c, 10; d, 20; e, 40.

Fig. 2 Platelet ^3H -cyclic GMP levels during release of ^{14}C -5-HT induced by collagen in the presence and absence of CB. Final CB and collagen concentrations were 10 and $5.4 \mu\text{g ml}^{-1}$ respectively when present. ^3H -Cyclic GMP values are means \pm s.e.m. from three identically treated samples of PRP. Closed symbols, ^3H -cyclic GMP (d.p.m.); open symbols, ^{14}C -5-HT released (%). \circ , \bullet , Controls without CB or collagen; Δ , ∇ , CB alone; ∇ , Δ , collagen alone; \diamond , \diamond , CB and collagen.

^{14}C -5-HT. CB (5 or $10 \mu\text{g ml}^{-1}$) had no statistically significant effect on basal ^3H -cyclic GMP levels or on the increases caused by moderate or high doses of collagen, although it markedly potentiated the release reaction induced by the former (Fig. 2, Table 2). These findings indicate that cyclic GMP does not mediate the potentiation of release by CB. With threshold doses of collagen, however, CB did increase ^3H -cyclic GMP to a highly significant extent (Table 2). This can be explained by the observation that addition of ADP alone also increased ^3H -cyclic GMP (Table 2). Thus, potentiation of the release of ADP by CB probably provided an important extracellular stimulus for the formation of ^3H -cyclic GMP, when little collagen was present. That collagen itself at higher concentrations also stimulates formation of cyclic GMP is indicated by previous observations that inhibition of collagen-induced release and aggregation by aspirin does not block the associated increase in platelet ^3H -cyclic GMP¹⁸. Addition of ADP with or without CB did not cause release of any platelet ^{14}C -5-HT (Table 2). Thus, even if an increase in cyclic GMP is necessary for the release reaction to occur, other factors provided by collagen but not ADP in heparinised PRP are also required. The results indicate that increases in ^3H -cyclic GMP in human platelets may be a relatively nonspecific response to stimulation. Whether platelet aggregation, the release reaction or other platelet activities are facilitated in the presence of increased intracellular cyclic GMP levels remains to be established.

If the potentiation of the release reaction by CB is not mediated by cyclic GMP, what other possibilities exist? It is conceivable that a single class of membrane binding sites could both inhibit glucose transport and facilitate the membrane fusion required for exocytosis²⁸. These membrane sites could be on a protein, possibly platelet actin or myosin, elsewhere associated with the contractile apparatus of the platelet in such a way that their affinity for CB is reduced^{29,30}. Interaction of CB with these latter sites would then account for the inhibitory action of the compound on platelet activities.

We thank Dr W. B. Turner of ICI Ltd, Pharmaceuticals

Division, Macclesfield, England for a sample of CB. This work was supported by grants from the Medical Research Council of Canada and the Ontario Heart Foundation.

Changed surface glycoprotein as a marker of malignancy in human leukaemic cells

A STRUCTURAL difference in fucose-containing glycopeptides isolated from the surface of virally transformed fibroblasts has been described^{1,2}. Further studies revealed that this difference was caused by increased sialic acid content of the glycopeptides³. Previously we demonstrated⁴ that this phenomenon is not limited to the surface glycoprotein of virally transformed fibroblasts but also occurs in spontaneously chemically or virally transformed cells of fibroblastic, epithelioid and lymphoid morphologies maintained *in vitro*. Since similar results were obtained with mouse lymphosarcoma and rat hepatoma cells grown *in vivo* (ref. 5 and manuscript in preparation), we have extended our observations to human tumour biopsies. We now report that analogous changes occur in the surface glycopeptides of tumour cells obtained from peripheral blood of patients with active leukaemia or with leukaemic transformation of lymphosarcoma. In all cases peripheral blood from untreated patients containing at least 80% leukaemic cells in the white blood cell fraction, were used.

Normal resting and phytohaemagglutinin (PHA) stimulated peripheral blood lymphocytes served as controls. Blood lymphocytes from patients in various stages of infectious mononucleosis (IM) were used as an additional control for a non-malignant lymphoproliferative disease.

Defibrinated blood samples were run on a Ficoll-Isopaque gradient⁶ and lymphocytes or blasts were collected

from the interphase, washed and counted (Tables 1 and 2: recovered white blood cells (WBC)). Enrichment in myelocytic leukaemic blasts by partial loss of differentiated cells is not excluded by this method. The washed cells were incubated in RPMI 1640 medium supplemented with 20% foetal calf serum and antibiotics in small Erlenmeyer flasks at a density of 4×10^6 cells ml⁻¹. The cells were differentially labelled by incubation for 2 or 3 d in the presence of ¹⁴C-fucose (0.25 μ Ci ml⁻¹) in the case of control lymphocytes or ³H-fucose (0.50 μ Ci ml⁻¹) in the case of tumour cells, IM cells or PHA-stimulated lymphocytes. PHA stimulation was carried out by the inclusion of the mitogen (50 μ g ml⁻¹) in the incubation medium.

Tumour cell numbers did not change during incubation and viability exceeded 90% as measured by trypan blue dye exclusion except in some cases of lymphosarcoma cells (patient 10, Table 1). After incubation, the cells were collected by centrifugation, washed and mildly trypsinised. The solubilised materials from control and tumour, IM or PHA-stimulated cell samples were mixed and exhaustively digested

Fig. 1 Elution profile of L-fucose-containing glycopeptides of pronase-digested trypsinates from differentially labelled PHA-stimulated (●) and resting normal (○) peripheral lymphocytes following filtration through Biogel P10–Sephadex G-50 fine (2:1). The radioactivity of the fractions is represented as percentages of total radioactivity eluted from the column. The column markers blue dextran (BD) and phenol red eluted from the column in fraction range 23–29 and 83–94 respectively.

with Pronase, followed by dialysis and concentration by lyophilisation. The resulting glycopeptides were filtrated over Biogel P10(200–400 mesh)–Sephadex G-50 fine (2:1) columns (1 × 100 cm).

Full experimental details including conditions of neuraminidase treatment of the glycopeptides have been published elsewhere⁴.

Cochromatography of the Pronase-digested, fucose-labelled glycopeptides obtained from resting and PHA-stimulated peripheral lymphocytes showed that the ascending limbs of the elution profiles coincided (Fig. 1). The main peak was increased, but not displaced, in the case of stimulated cells at the expense of lower molecular weight material, similar to the difference observed in log and plateau phase fibroblasts⁷.

Fig. 2 Elution profile of L-fucose-containing glycopeptides of Pronase-digested trypsinates from differentially labelled peripheral leukaemic cells from patient 4 (Table 1) with CLL (●) and from normal peripheral lymphocytes (○) following filtration through Biogel P10–Sephadex G-50 fine (2:1). The radioactivity of the fractions is represented as percentages of total radioactivity eluted from the column. The column markers blue dextran (BD) and phenol red eluted from the column in fraction range 26–31 and 87–96 respectively.

The results of cochromatography of malignant and normal lymphocyte glycopeptides are summarised in Table 1. In all experiments, including a permanent line of Burkitt's lymphoma (not illustrated), the fucose-labelled glycopeptides of the malignant cells eluted ahead of the controls. The degree of this horizontal displacement was estimated at half-maximal height of the ascending limb of the profiles and expressed as the number of fractions eluting ahead of the control. The difference is represented in Table 1 by the corresponding number of (+) signs. Differences among the elution profiles of individual malignant cell samples were

Fig. 3 Elution profiles of L-fucose-containing glycopeptides of Pronase-digested trypsinates from differentially labelled peripheral leukaemic cells from patient 5 (Table 1) with AML (●) and from normal peripheral lymphocytes (○) before (a) and after (b) neuraminidase treatment following filtration through Biogel P10–Sephadex G-50 fine (2:1). The radioactivity of the fractions is represented as percentages of total radioactivity eluted from the column. The column markers blue dextran (BD) and phenol red eluted from the column in fraction range 28–33 and 99–107 respectively.

noted not only in the degree of horizontal displacement but also in the overall shape of the profile, as similarly observed earlier for various transformed cell lines *in vitro*⁶. Thus, the glycopeptides from chronic lymphocytic leukaemia (CLL) cells simply eluted ahead (Fig. 2), whereas AML (acute myelocytic leukaemia) glycopeptides showed a discrete peak ahead of the main peak of the control (Fig. 3a). It remains to be established whether details of elution profiles correlate with the type of the disease.

The glycopeptides of nine cell samples, each mixed with control glycopeptides, were incubated with *Vibrio cholerae* neuraminidase (Behringer, 50 U ml⁻¹, for 120 min) before cochromatography. In seven cases, the enzyme treatment eliminated the difference in the elution profiles between tumour and normal samples (0, Table 1; Fig. 3b) or caused tumour glycopeptides to elute after the controls by one fraction (—, Table 1). From similar results with cultured normal and transformed cells it has been concluded previously that an increase of neuraminidase-sensitive sialic acid in the transformed-cell glycopeptides is responsible for their being eluted ahead of the corresponding normal material^{3,4}. Apparently the same molecular change occurs in the glycopeptides obtained from the human leukaemic cells studied here.

It may be significant that only in the two cases of chronic myelocytic leukaemia (CML) cells no 'normalisation' of the elution profiles by neuraminidase treatment was obtained. Unpublished results with certain experimental

tumours suggest that in such cases either neuraminidase-insensitive sialic acid or an additional anionic (sulphated or phosphorylated) sugar residue could be involved. Further experiments are needed to establish whether CML cells may be distinguished from other leukaemia cases by this criterion and to investigate the determinant of the higher apparent molecular weight of the glycopeptides from these cells.

At the time of the assay, the diagnosis of patient 7 (Table 1) was uncertain. He was suspected of having leukaemia but since the Paul Bunnell test was positive, the possibility of IM could not be excluded. The elution profile of the surface glycopeptides indicated similarity with malignant disease. In the further course of the disease the patient developed the typical clinical picture of CML of the juvenile type.

This result prompted the investigation of lymphocytes from patients with IM. In all 10 cases studied (Table 2), the elution profiles of the glycopeptides coincided with controls of normal lymphocytes or exhibited a small shift to lower molecular weight regions (Fig. 4). Neuraminidase did not materially change the relative elution behaviour of the IM and normal glycopeptides.

The Pronase-digested, fucose-labelled glycopeptides obtained by mild trypsinisation of human leukaemic and lymphosarcoma cells consistently eluted ahead of the corresponding materials from resting or PHA-stimulated lymphocytes. The absence of such difference between resting and PHA-stimulated peripheral lymphocytes (Fig. 1) excludes the possibility that the change in tumour glycopeptides is due to blastoid transformation. The finding that glycopeptides from IM cells eluted together with or slightly after those from normal lymphocytes is further indication that the different behaviour of leukaemic cells is associated with their malignant character. Moreover, it excludes the possibility that the behaviour of the malignant lymphocytes is only the result of the presence of a high count of leukocytes in the peripheral blood since comparable or even higher counts were observed in IM patients. Also, the structural change in surface glycoprotein was consistently found in all malignant cell samples irrespective of their assumed origin as B cells (CLL Burkitt's lymphoma) or as T cells (childhood lymphosarcoma) whereas ALL (acute lymphocytic leukaemia), CML and AML cells lack B and T markers⁸.

Fig. 4 Elution profile of L-fucose-containing glycopeptides of Pronase-digested trypsinates, from differentially labelled peripheral lymphocytes from patient 3 (Table 2) with infectious mononucleosis (●) and from normal peripheral lymphocytes (○) following filtration through Biogel P10–Sephadex G-50 fine (2:1). The radioactivity of the fractions is represented as percentages of total radioactivity eluted from the column. The column markers blue dextran (BD) and phenol red eluted from the column in fraction range 28–33 and 86–94 respectively.

Thus we conclude that surface glycoprotein composition in human leukaemic and lymphosarcoma cells is characteristically changed relative to normal; that except for CML this change is due to an increased content of neuraminidase-sensitive sialic acid; and that the difference is observed in all transformed and malignant cells studied so far, irrespective of the cell type, natural history of the cell, species or oncogenic determinant. This glycoprotein change may be a universal property of tumour cells and related to the expression of the neoplastic phenotype. If not instrumental in neoplastic behaviour, it may at least have diagnostic value.

Finally, we want to point out that the experimental device used here monitors only a minor part of the sialoglycoprotein of the cell surface⁴. Therefore, our observations do not necessarily correlate with other changes observed in the total sialic acid content or its exposition on the cell surface, let alone that in these respects no universal changes have been observed in tumour cells^{9,10}.

We thank Mr J. Breckveldt for technical assistance and Miss Joke Blok and Mr H. van Rooy for their help in tissue culture experiments and Miss Loes Pullens, Mrs Mary Geel and Mrs Anneke van Dongen for collecting blood samples.

Peripheral blood from untreated patients and their diagnoses were kindly provided by Drs A. Voûte, F. Cleton, R. Somers and K. Roozendaal, Amsterdam. Peripheral blood from patients with infectious mononucleosis was obtained by courtesy of the Huisartsenlaboratoria Van der Baan and Amstelland, Amsterdam, and the Huisartsenlaboratorium, Utrecht.

Detoxifying effect of yellow substance on *E. coli* in media containing copper

DISSOLVED yellow organic matter (yellow substance) is ubiquitous in aquatic systems, and is thought to influence the state of ecosystems by affecting the transport and fate of minerals, primary production and, perhaps, the behaviour of aquatic organisms¹⁻⁴. Although much studied, yellow substance remains chemically and physically ill-defined. It is primarily responsible for the yellow colour of particulate-free natural waters which is generally accepted to be the result of the aqueous extract of decaying plant material. One of the primary constituents of plant material, lignin, is the precursor of a class of stable, yellow-brown, intermediate decay products called humins or humic substance⁵. Divided into two fractions, humic acid (base soluble) and fulvic acid (acid soluble), these compounds are insoluble in water and are typically analysed as extracts from soil or sediment. Yellow substance is the remaining yellow decay product and is often called soluble humin (dissolved humic acid). There are data, particularly differences in elemental

composition and visible and ultraviolet light absorption, however, suggesting that yellow substance is a separate compound with cellulose as its source rather than lignin⁶.

There have been two attempts to establish a direct biological role for yellow substance. Prakash and Rashid^{7,8} observed moderate enhancement of growth of various phytoplankton in cultures spiked with yellow substance (referred to as dissolved humic acid in this work); and, in similar experiments, Shapiro¹ reported possible growth enhancement in cultures of several algae. Other findings suggest an interaction with metals in the aquatic ecosystem⁷. Horne and Goldman⁸ reported the suppression of nitrogen fixation in blue-green algae by copper ions (Cu^{2+}). Jones⁹ postulated that metal ions, particularly Cu^{2+} in seawater media suppress *Escherichia coli* in that system. Erickson^{10,11} obtained similar results with *Thalassiosira pseudonana* with the added inference that decomposed natural plankton and detritus, possibly yielding natural chelators¹², reduced Cu^{2+} toxicity. We have now found that although yellow substance plays no direct role in population growth of *E. coli*, it does ameliorate the effects of Cu^{2+} added to the system in toxic concentrations.

Fig. 1 Chromatogram of parent yellow substance used in this study. Flow rate was 11 ml h^{-1} . Fraction I, recovered at the exclusion limit, was colourless and was not included with parent yellow substance (II-IV).

Yellow substance was obtained from Millipore-filtered ($0.2 \mu\text{m}$) water from the upper Russian River in northern California in October 1973. Isolation was accomplished by ion exchange techniques designed to handle large volumes¹³. Further purification for removal of trace organic material such as free amino acids was accomplished by gel filtration on a 200-cm column of Sephadex G-50 with 0.02 M NaCl as eluant. Resulting chromatograms indicated the possibility of three major fractions (Fig. 1). Comparison of chromatograms of yellow substance obtained on Sephadex G-25 and G-50 with some known standards and with the exclusion limits of the gels indicates an approximate average molecular weight of 5,000. Amicon (UM-02) filtration and lyophilisation yielded an electrolyte-free product which represented approximately 0.001% of the mass of the original filtered water sample.

Cultures of *E. coli* W 1485 (ref. 14) were prepared in a medium containing, (g l^{-1}), K_2HPO_4 , 10.5; KH_2PO_4 , 4.5; MgSO_4 , 1.0; NH_4Cl , 1.0; and glucose, 2.0. The bacteria were cultured aerobically at 37°C with sterile conditions maintained throughout. Cell density was measured by absorbance at 650 nm with a Cary 16 spectrophotometer. For the experiments, all cultures were diluted to an initial optical density of 0.008. After an initial static period, cultures grew exponentially with a mean doubling time of $66.0 \pm 0.9 \text{ min}$ (average and standard deviation of 20 independent cultures). Growth was followed by absorbance measurement every 30 min out to an A_{650} reading of 0.4, representing approximately six generations of reproduction.

To measure the effects of yellow substance on the growth of the population we added it to the culture medium in con-

Received November 19; revised December 20, 1974.

Fig. 2 *a*, Growth of *E. coli* in control media. *b-d*, Growth of *E. coli* in media made toxic with 6×10^{-6} M Cu^{2+} with additions of equimolar EDTA (*b*), yellow substance (*c*), citrate (*d*). *e*, Growth of *E. coli* in toxic control (6×10^{-6} M Cu^{2+}).

concentrations of 10^{-6} to 10^{-4} M, assuming an average molecular weight of 5,000 for the yellow substance. Doubling time was not affected by yellow substance. When glucose was replaced by yellow substance, growth stopped.

To investigate the influence of yellow substance on growth in media made toxic with cupric ions, we first established the growth suppressant effect of cupric ions on our *E. coli* system by measuring doubling times in cultures to which CuSO_4 (ultrapure, Johnson, Matthey and Co.) had been added at concentrations of 10^{-4} – 10^{-6} M. There was no growth in the presence of 10^{-4} M Cu^{2+} . At 6×10^{-6} M, growth remained linear but at a substantially reduced doubling time of 108 ± 2.2 min (Fig. 2).

The detoxifying effect of sodium citrate, EDTA and yellow substance was measured in the system made toxic with 6×10^{-6} M Cu^{2+} (Fig. 2). Concentrations of yellow substance of 10^{-5} M significantly enhanced growth rate beyond the toxic control (86 min doubling time compared with 108). Comparison of the doubling time with equimolar EDTA (76 min) and sodium citrate (108 min), indicate that yellow substance is considerably more effective in ameliorating Cu^{2+} toxicity than citrate and comparable with EDTA.

These results suggest that yellow substance should be considered as a prime moderator of metal ion availability to microorganisms in aquatic ecosystems. To ascertain the ultimate influence of yellow substance on ecosystems would require extensive investigation of the effects of the alteration of pH and redox potential on the results we have observed.

A simple cytochemical technique for demonstration of DNA in cells infected with mycoplasmas and viruses

4'-6-DIAMIDINO-2-PHENYLINDOLE (DAPI), which was first synthesised by Dann *et al.*¹ as a trypanocide related to Berenil, has been shown to possess useful DNA binding properties². Thus, DAPI will bind differentially to yeast mitochondrial and nuclear DNA forming highly fluorescent complexes and enhancing the separation of the two DNAs in caesium chloride gradients². DAPI can also be used as a highly specific fluorescent stain for both nuclear and mitochondrial DNA in yeast. It seems to be highly sensitive and probably permits detection of a single yeast mitochondrial DNA molecule (D.H.W., and D. J. Fennell, unpublished).

We have investigated the use of DAPI in tissue culture systems and have found that it offers a very simple and sensitive procedure for detecting mycoplasma contamination.

Mycoplasmas are a major source of contamination of many cell lines carried in the laboratory, and there are many techniques available for detecting them (for review see ref. 3). Most of these methods are relatively lengthy and involve either cultivation of the mycoplasmas in special broth or agar, rather subjective assessments by cytochemical techniques, or some biochemical measurements often quite complex in nature. Probably the most sensitive and least ambiguous method presently available for the detection of mycoplasmas in tissue culture is that which uses the incorporation of ^3H -thymidine followed by autoradiography of the labelled cells⁴. Discrete and characteristic grains in the cytoplasm and on the cell surface are indicative of the presence of mycoplasmas. This method however, while sensitive and relatively straightforward, does not give the often necessary rapid diagnosis. We have thus developed a procedure for detecting mycoplasmas in tissue culture using DAPI which seems to have all the attributes of the autoradiographic method but is quicker and simpler.

On adding DAPI to tissue culture cells we found that it was rapidly taken up into cellular DNA yielding highly fluorescent nuclei and no detectable cytoplasmic fluorescence under the conditions used (Fig. 1a). If, however, the cells were contaminated with mycoplasmas, characteristic discrete fluorescent foci were readily detected in the cytoplasm and on the surfaces of the cells (Fig. 1b). Similarly, DAPI staining of cells infected with vaccinia virus revealed characteristic fluorescent virus 'factories' in the cytoplasm (Fig. 1c). The method has been applied to a variety of tissue culture cells (HeLa, KB, BHK21, MDBK, LLCMK2) and in all cases where mycoplasmas could be detected by the conventional technique of agar cultivation⁵, cytoplasmic fluorescence was readily observed. In some cases, moreover,

Fig. 1 *a*, Photomicrograph of control, unfixed and uncontaminated HeLa cells, treated with DAPI ($0.1 \mu\text{g ml}^{-1}$) at 37°C for 1 h. Fluorescent nuclei with some mitotic figures can be observed. *b*, Photomicrograph of unfixed, mycoplasma-contaminated HeLa cells treated with DAPI as in *a*. Characteristic cytoplasmic fluorescence can be seen; on refocusing on a different plane, the apparent intense nuclear fluorescence can be seen to be mainly cytoplasmic. *c*, Photomicrograph of unfixed HeLa cells 3 h after infection with vaccinia virus (at an added multiplicity of about 5 PFU per cell). Characteristic 'star-like' fluorescent clusters of presumably maturing virus in 'factories' can be observed ($\times 1,225$).

where there was no clear evidence by agar cultivation, cytoplasmic fluorescence could be observed in a minority of cells, probably indicative of a low level of mycoplasma contamination. A variety of conditions for the incorporation of DAPI into the tissue culture cells were examined, and while it seemed that a fairly wide spectrum of pH, ionic strength and concentration of DAPI could be used, the following simple procedure has been applied on a routine basis for monitoring cells for mycoplasma contamination.

Monolayers of cells grown on coverslips were washed once with phosphate buffered saline (PBS) and incubated in a small volume of PBS containing DAPI at a concentration of $0.1 \mu\text{g ml}^{-1}$ at 37°C for 15–30 min. The coverslip was again washed once with PBS and inverted (without fixation) on a microscope slide and examined in a fluorescence microscope (with a high pressure mercury vapour lamp as a source—for example, Vickers M41 Photoplan—with excitation frequency about 365 nm and emission principally about 450 nm). By lengthening the period of incubation in the presence of DAPI, the intensity of fluorescence in the

nuclei can be increased; with the shorter period of incubation there is less nuclear fluorescence and any cytoplasmic fluorescence is more easily monitored. Background fluorescence is minimal and thus there is no difficulty in discerning fluorescent DNA-DAPI complexes. That the fluorescent foci detected could be attributed to mycoplasmas was tested by deliberately infecting an uncontaminated line of HeLa cells. Mycoplasmas (*Mycoplasma fermentans* PG18) were grown in broth culture and titrated using the indicator techniques as previously described³. Monolayers of cells were infected at different added multiplicities and examined at various stages after infection and also after subcultivation of the cells. By using the DAPI technique it was possible both to follow the course of the mycoplasma infection of the cells and also to detect mycoplasmas in the broth cultures. The uninfected cells always gave negative cytoplasmic fluorescence during these procedures while the infected cells showed varying degrees and distribution of the characteristic cytoplasmic fluorescence.

This technique is extremely simple and can be readily applied to monitor tissue culture cells for mycoplasma contamination. Our observations also suggest that the technique may be more sensitive than conventional cultivation techniques and, of course, a cytochemical test obviates the requirements for fastidious culture media. The method should also be useful as a more general tool for monitoring the distribution and properties of DNA in a variety of biological contexts; for example, the course of vaccinia virus infection (Fig. 1c), as the virus matures in the cytoplasm, can be followed readily. We have also successfully used DAPI to follow the fate of inoculum adenovirus at early stages of infection.

We thank Professor Otto Dann of the Institut für Angewandte Chemie der Friedrich-Alexander-Universität, Schuhstrasse 19, 852 Erlangen, West Germany, for gifts of DAPI (from whom research samples may be obtained). We thank Mr M. R. Young for preparing the photomicrographs.

Note added in proof: Since submitting this letter, we have used as an alternative to DAPI, the fluorescent DNA-binding benzimidazole derivative Hoechst 33258 (ref. 6) with broadly similar results.

Biosynthesis and degradation of methylmercury in human faeces

MERCURY is transformed by the microorganisms present in aquatic sediments¹ and rat intestines². Examples of some of the important reactions are illustrated below.

Divalent mercury is reduced to elemental mercury (Hg^0)

aerobically and alkylated to methylmercury (CH_3Hg^+) anaerobically. Methylmercury can be demethylated to Hg^0 and CH_4 aerobically or anaerobically. Methylmercury is of great concern to man because it is highly toxic, is absorbed through the intestinal wall 45 times more rapidly than Hg^{2+} (ref. 3) and is retained in the body longer than Hg^{2+} . The ingestion of food contaminated with methylmercury has resulted in severe outbreaks of mercury poisoning in Minamata, Japan, Alamogordo, New Mexico, and Iran. The ability of bacteria to alkylate mercury prompted us to investigate whether the normal microbial flora of the human intestine could synthesise methylmercury and thus contribute to the body burden of this noxious compound.

Samples of freshly voided human faeces were weighed and placed immediately in anaerobic culture tubes (Bellco glass). Previously reduced culture medium⁴ was added to make a 25% (w/v) suspension of the faecal matter. To avoid killing oxygen sensitive anaerobes, all manipulations were performed in an oxygen-free environment using procedures described by Hungate⁵. The faecal suspensions were gassed with a mixture of H_2 and CO_2 and isolated from air with rubber stoppers. The required amount of $^{203}\text{HgCl}_2$ (New England Nuclear Corp.) or $^{14}\text{CH}_3\text{HgCl}$ (NEN) was added to the gassed mixtures and rapidly mixed. The samples were incubated at 37°C in a shaking water bath. Methane synthesised by the faecal bacteria was measured by gas chromatography on a silicic acid column.

Fig. 1 Concentration of methylmercury in faeces after addition of 5×10^{-7} M HgCl_2 (Δ); 1×10^{-6} M HgCl_2 (\blacklozenge); and 7×10^{-6} M HgCl_2 (\bullet).

Methylmercury was extracted from the faecal suspension by the combined mercuric chloride–cysteine acetate method of Westöö⁶. One millilitre of the sample was placed in a centrifuge tube together with 1 ml HgCl_2 (5%, w/v); 1 ml 6N HCl, and 2 ml benzene. The sample was mixed vigorously for 1 min and then centrifuged at $3,000g$ for 5 min at room temperature. The upper (benzene) layer was removed and mixed vigorously with 0.5 ml of 1% cysteine acetate for 1 min. The aqueous layer was removed and mixed thoroughly with 0.2 ml of 6N HCl and 1.0 ml of benzene. The benzene layer was mixed with anhydrous sodium sulphate to remove water.

Methylmercury was identified by thin-layer chromatography of the cyanide and iodide salts. The cyanide salt was made by mixing the benzene layer from the cysteine acetate extraction with 0.5 ml of 1M KCN. The cyanide

Fig. 2 Disappearance of $^{14}\text{CH}_3\text{Hg}^+$ from faeces. Initial methylmercury concentration was 3.1×10^{-6} M. The $^{14}\text{CH}_3\text{Hg}^+$ was added to anaerobic tubes containing 10 ml of diluted faeces. The tubes were gassed with $\text{H}_2 : \text{CO}_2$ (80 : 20) and incubated at 37°C . One ml samples were withdrawn and extracted for methylmercury as described.

derivative was then chromatographed on silica gel G by thin-layer chromatography using diethyl ether–toluene (90 : 10, v/v) as the developer. Methylmercury was visualised by spraying with 0.4% (w/v) dithizone in benzene. To verify further that the compound in question was methylmercury, the benzene layer was mixed with NaI and chromatographed using light petroleum–diethyl ether (70 : 30) as the developer. The presence of ^{14}C -methylmercury or ^{203}Hg -methylmercury (isotopic methylmercury) was established either by scanning the chromatographic sheets in an actigraph (Nuclear-Chicago) or by counting the amount of isotope in silica gel scraped from the sheets.

Methylmercury was produced when faecal matter was incubated anaerobically with $^{203}\text{HgCl}_2$ (Fig. 1). Maximum levels of methylmercury were produced during the first 2 d of incubation followed by a rapid decline. This type of production pattern was repeated in every sample examined, although the peak sometimes appeared as early as 18 h. The amount of methylmercury produced was directly proportional to the amount of Hg^{2+} added. In this experiment the amount of radioisotope was held constant and the amount of non-radioactive Hg^{2+} was varied. No dilution effect was observed, suggesting that a significant proportion of the Hg^{2+} was unavailable for methylation, probably because it was immobilised as the very insoluble sulphide derivative. It is interesting that there was no correlation between methane and methylmercury biosynthesis. Wood *et al.*⁷ reported that cell-free extracts of the methanogenic bacterium *Methanobacterium* strain M.o.H. could catalyse the alkylation of Hg^{2+} . Samples which did not synthesise methane, however, still yielded high levels of methylmercury.

The rapid loss of methylmercury from the samples prompted an investigation into the half-life of the compound in the faeces. These experiments were performed by following the disappearance of a known amount of added $^{14}\text{CH}_3\text{Hg}^+$. As Fig. 2 shows, $^{14}\text{CH}_3\text{Hg}^+$ disappeared at a constant rate during the 7-d test. Thus, either by chemical or biological means, methylmercury can be degraded in an anaerobic faecal specimen. $^{14}\text{CH}_4$ was not observed, thus loss is not the result of reductive demethylation.

These studies are evidence that the microbial flora of the intestine of man has the potential to transform Hg^{2+} to highly toxic methylmercury and could contribute significantly to the methylmercury burden of the body and thereby

add to the risk of incurring or increasing the severity of methylmercury poisoning.

Citrate in milk: a harbinger of lactogenesis

CONSIDERABLE amounts of citrate (130-160 mg per 100 ml) occur in the milk of cows and goats, and approximately half this amount in that of women. In spite of its central role in the metabolism of all cells, the significance of the presence of citrate in milk and its mode of secretion are not known¹. We report that the final stage of lactogenesis is preceded by the onset of citrate secretion into colostrum.

Matured but previously quiescent epithelial cells suddenly start to secrete large quantities of protein, fat and carbohydrate at about the time of parturition. Although there are significant changes in plasma hormone concentrations in late pregnancy and at term, the nature of this lactogenic trigger remains unknown^{1,2}. Cowie and Tindal³ have suggested that the presence

Fig. 1 Concentrations of citrate in the mammary secretion of *a*, a cow; *b*, a goat; and *c*, a woman about the time of parturition. Small samples were taken from the teat and analysed by the method of White and Davies¹⁰. In all species the young were suckled normally after parturition.

in the secretory tissue of the relevant organelles, enzymes, substrates and some specific milk components, is not sufficient evidence for the onset of copious secretion. For example, udders of cows and goats may contain several litres of a fluid with almost normal milk lactose and ion concentrations 6-7 weeks before term, although copious secretion starts at about the time of parturition (ref. 3 and I. R. Fleet, J. A. Goode, M. H. Hamon, M. S. Laurie, J. L. L., and M. P., unpublished). The onset of secretory activity therefore occurs in two stages, and other investigations^{4,5} have in fact only covered the first stage^{4,5}.

The rate of onset of copious secretion is indeed impressive; in cows the yield may be as high as 40 l d⁻¹ within a few days after parturition and 4 l d⁻¹ in goats. The mammary glands need about 70 g glucose per litre milk formed to support secretion⁶, and although mammary blood flow increases markedly before parturition in goats and cows^{7,8} the uptake of glucose and oxygen does not begin until immediately after parturition and then reaches high levels within a few hours⁸.

In milk from seven goats and seven cows, citrate concentration increased by 3-150 times (median for goats 10 times, for cows 46 times) 1-2 d pre-partum and 2-3 d post-partum (Fig. 1). This rapid increase is illustrated by data from a cow in which the citrate concentration increased from 7 to 110 mg per 100 ml in the last 5 h of pregnancy. In women the onset of copious milk secretion does not begin until 3-4 d post-partum⁹, and it is significant that citrate in samples of secretion obtained from the wife of a colleague on the day of delivery was low and then increased to reach a peak on day 4 (Fig. 1).

Milk citrate is synthesised from glucose and acetate in the mammary gland of the goat⁹. The sudden marked increase in citrate thus indicates not only the onset of synthesis and secretion of this substance but of copious secretion as well.

We thank Maureen Hamon, who carried out the analyses and Mrs I. C. Johnson who obtained the human milk samples; and P. F. Bridge, P. W. Jones, H. H. Pope and Miss A. Schwabe for help with collecting cow samples.

Isoenzymes of hexokinase in human muscular dystrophy

OF the several genetically determined diseases called muscular dystrophy, the best known, most studied and most severe are the sex-linked Duchenne type and its more slowly progressing variant, the Becker type¹. The aetiology of these dystrophies is unknown, although dystrophies associated with deficiencies of vitamins and other nutrients are known in animals, and myopathy in man may arise from causes as diverse as alcoholism, thyrotoxicosis, infection and autoimmunity². Such variety of known myopathies gave little help to early searches for the biochemical cause of the genetically determined dystrophies³. Recent workers have turned to biochemistry in search of a specific lesion in protein synthesis and its control⁴⁻⁶, or to tissues other than muscle, for example, its motor innervation⁷⁻¹⁰ or vascular supply¹¹. Clearly, a genetic lesion must be translated

into some change in protein synthesis, but this change will have other effects which will probably be more readily detectable. Other tissues besides muscle will be subject to the genetic changes which determine dystrophy, and may also show pathological signs.

Our belief is that dystrophic skeletal muscle will have specific properties from which the primary lesion(s) may be deduced. We have found that in dystrophic muscle, more glucose than usual is converted to fructose instead of to glucose 6-phosphate, under certain metabolic conditions^{12,13}. The conversion of glucose to glucose 6-phosphate is catalysed by hexokinase (EC 2.7.1.1.) which is present in mammalian tissue in one or more of several electrophoretically distinguishable isoenzymes differing considerably in their respective K_m values for glucose¹⁴⁻¹⁶.

Hexokinase activity has previously been measured in extracts of normal and dystrophic human muscle¹⁷⁻¹⁹, and seems to be present in adequate amounts in the test tube at

Fig. 1 Hexokinase isoenzymes of normal human tissues. Tissue samples (50–200 mg) were homogenised in 2–20 volumes of 0.1 M Tris, pH 7.4 containing EDTA (5 mM) and glucose (10^{-6} M). Homogenates were centrifuged for 6,000,000 g min. Supernatants were used directly for electrophoresis on Cellogel strips (Reeve Angel, London) at 200 V for 1 h in 0.02 M sodium barbital buffer, pH 8.4 containing EDTA (2.7 mM). All these procedures were carried out at 4°C. Staining strips for protein was carried out for 5 min in a solution of 0.2 g Ponceau S and 3 g trichloroacetic acid in 100 ml water. Staining of hexokinase activity took place at three different glucose concentrations for each extract, namely 10^{-2} M, 5×10^{-4} M and 10^{-6} M, according to the method of Katzen, Soderman and Wiley¹⁵. Supernatants were also concentrated tenfold using Minicon polymer blocks (Amicon Ltd, High Wycombe, UK) and again subjected to electrophoresis so that faintly-staining bands should not be overlooked. Bands of hexokinase activity were referred for comparison to the albumin band of the strip stained for protein. The degree of activity is represented by the density of shading. Tissue was used either fresh or after storage at -70°C . Liver and nerve were autopsy specimens. Muscle (four spinalis; six latissimus dorsi) was obtained during orthopaedic operations, and connective tissue and adipose tissue used in this study were trimmed from around such muscle specimens. Foetal muscle was obtained from embryos at therapeutic abortion at 14–18 weeks gestation. Isoenzymes are classified according to Katzen *et al.*¹⁵. The number of specimens used is given in parentheses. There was no detectable difference in the isoenzyme patterns of spinalis and latissimus dorsi muscles.

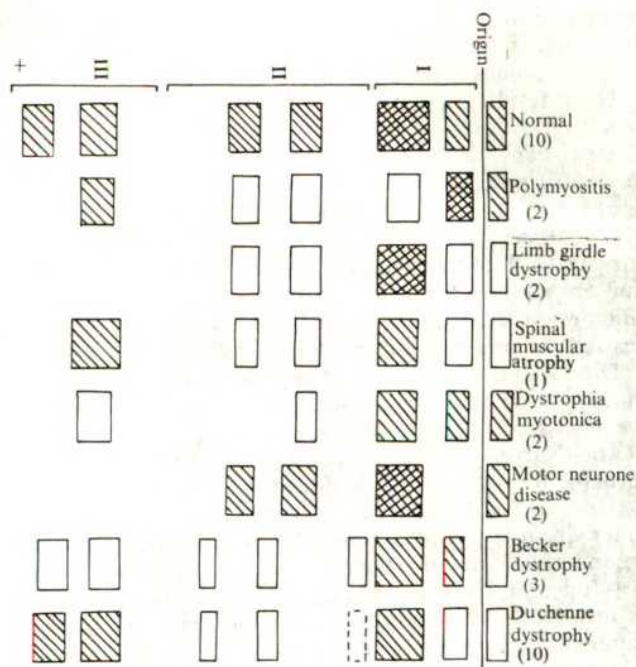

Fig. 2 Hexokinase isoenzymes in human muscle in health and disease. Specimens (10–100 mg) from diagnostic muscle biopsies were all obtained from deltoid, except for four patients with Duchenne dystrophy and two with Becker dystrophy in which the site of biopsy was gastrocnemius. Deltoid muscle was obtained at autopsy from three patients dying at age 18–20 yr from the effects of Duchenne dystrophy. These muscles were grossly affected, and muscle fibres were dissected from the surrounding fibrous and fatty tissue under magnification. The remaining patients with Duchenne dystrophy aged 6–10 yr were still ambulant; microscopic examination of the muscle showed active myopathy. The patients with Becker dystrophy were aged 8–18 yr, all actively ambulant, and showed early myopathic histopathology. Other patients used as controls were of widely differing ages. Treatment of specimens was otherwise as for Fig. 1.

the high glucose concentrations used. We examined the isoenzyme patterns of hexokinase in a variety of tissue samples. Figure 1 shows the normal isoenzymes of human tissues, illustrating the variation in isoenzyme constitution between tissues but the constant electrophoretic mobilities of the bands concerned. Figure 2 demonstrates that the isoenzymes of diseased muscle, while varying in amount, do not differ from the normal isoenzymes in mobility, except in the case of the X-linked dystrophies of Duchenne and Becker. Normally, isoenzyme II consists of two bands on Cellogel, but in X-linked dystrophy there are three, two of which move faster than the bands of normal isoenzyme II, and one more slowly moving band close to isoenzyme I. Isoenzyme II is invariably weakly staining in these X-linked dystrophies, and is sometimes seen only after concentrating the extract. These differences indicate that the protein reacting as isoenzyme II in X-linked dystrophy differs from the normal isoenzyme II. As this isoenzyme is characteristically abundant in skeletal muscle, the change in its properties in dystrophy may be very significant. The alteration in isoenzyme II is not the consequence of adulteration with adipose or connective tissue, nor of reversion to foetal protein type, as these tissues contain only normal isoenzyme II. Furthermore, the change in isoenzyme II has also been shown in three livers, one brain and one sciatic nerve obtained *post mortem* from patients affected with Duchenne dystrophy, and from muscle and liver from a foetus of 18 weeks presumed to have Duchenne dystrophy.

In mixed extracts of normal and dystrophic muscle, the electrophoretic patterns of each constituent tissue were preserved. It was not possible to resolve the normal iso-

- enzyme II bands from the slowest and medium bands of dystrophic muscle isoenzyme II but the fastest band of dystrophic muscle isoenzyme II was clearly resolved.

These results suggest that the phenomenon expresses the genetic constitution of the tissues and is not the result of changes consequent upon disease, although it might be a secondary reflection of a yet more general genetic manifestation. Taken in conjunction with our other results^{12,13} it seems more likely that this alteration in hexokinase isoenzyme II, if confirmed, may imply a direct genetic alteration in its catalytic properties, possibly in its substrate affinities, which might restrict glucose flow through the hexokinase step in tissues where isoenzyme II is required.

This would then account for the observed fructose shunt^{12,13} and suggests an aetiology which could embrace the neurogenic⁷, myogenic²⁰ and even the vascular⁸ hypotheses. Nerve damage would be expected to occur from sorbitol formation, as described by Ward, Baker and Davies²¹ in diabetes; muscle would, as suggested earlier^{12,13} suffer from a gradual deposition of triglyceride in and around the fibres; deleterious effects on arterial or capillary function might be envisaged. The involvement of liver as mentioned by Thomson²² would be expected, while the pattern of muscular weakness and degeneration as described macroscopically by Bonsett²³ and microscopically by others^{24,25} would follow if the pathological changes were related to the effects of metabolism of glucose by muscle rather than alternative substrates, such metabolism being consequent on muscular activity²⁶.

We thank the Muscular Dystrophy Group of Great Britain for financial support.

Possible role of prostaglandin F_{2α} in mediating effect of prolactin on RNA synthesis in mammary gland explants of mice

Cyclic nucleotides seem to be intimately involved in the initiation of lactation and the consequent production of milk substances in the mammary gland¹⁻⁵. The ratio of cyclic GMP

to cyclic AMP increased several-fold in mammary glands taken from rats immediately after parturition and during lactation^{1,2}. Further, dibutyl cyclic AMP attenuated or abolished several hormone effects on enzyme activities and other metabolic events in explants from mid-pregnant rats³. It seems that the regulation of the metabolism of the mammary glands of mice may be specifically related to the mechanism whereby prolactin affects this tissue^{4,5}: cyclic GMP mimicked the early action of prolactin on RNA synthesis in mammary gland explants, whereas dibutyl cyclic AMP and agents which inhibit phosphodiesterase abolished this effect. These observations suggest that the early effect of prolactin on RNA synthesis is mediated by an elevated level of cyclic GMP and a reduced or maintained level of cyclic AMP.

Table 1 Effect of various combinations of prolactin, PGF_{2α}, PGE₁, PGA₂ and indomethacin on RNA synthesis in mouse mammary gland explants

Agent added	³ H-uridine incorporation into RNA (d.p.m. per µg RNA)			
	Control	Prolactin	Agent	Agent + prolactin
PGF _{2α}	216 ± 18	395 ± 27	354 ± 18	353 ± 18
PGE ₁	193 ± 16	285 ± 22	182 ± 10	181 ± 19
PGA ₂	198 ± 23	392 ± 28	173 ± 21	171 ± 21
Indomethacin	275 ± 24	462 ± 36	280 ± 32	332 ± 36

Mammary gland explants from mid-pregnant Swiss-Webster mice were preincubated for 2 d in medium 199 containing insulin (2.5 µg ml⁻¹) and hydrocortisone (2.5 µg ml⁻¹) by methods described previously⁷. A PG (50 µg ml⁻¹), indomethacin (10 µg ml⁻¹) and/or prolactin (2.5 µg ml⁻¹) were then added to the explants and incubation was continued for 4 h. ³H-uridine (1 µCi ml⁻¹, 5 Ci mmol⁻¹) was added to the flasks 30 min before terminating the incubations. The specific activity of ³H in the tissue RNA was determined as before⁷.

Numbers are means ± s.e. of explants from seven flasks.

Several investigators have postulated⁶ that the actions of the prostaglandins (PGs) in several biological systems are mediated by cyclic nucleotides. Specifically, it has been postulated that the actions of the PGs of the F series are mediated by cyclic GMP while those of the E and A series are mediated by cyclic AMP. I have therefore tested whether the PGs of the A, E and F series would mimic or attenuate the effect of prolactin on RNA synthesis in mouse mammary gland explants. Table 1 shows that PGF_{2α} mimicked the action of prolactin on RNA synthesis while PGE and PGA₂ abolished the prolactin effect. Moreover, since maximally stimulatory concentrations of prolactin and PGF_{2α} were used, the non-additivity of the two effects is compatible with the possible mediatory role of PGF_{2α} for prolactin. The abolition of the prolactin effect by PGE₁ and PGA₂ may be the result of stimulation of adenylyl cyclase⁶ with a consequent enhanced rate of synthesis of cyclic AMP.

Since indomethacin is known to inhibit prostaglandin synthesis through inhibition of the prostaglandin synthetase enzyme, I tested the effect of this drug on the prolactin stimulation of RNA synthesis. Table 1 shows that indomethacin abolished the prolactin effect. These data, therefore, further support the hypothesis that the effect of prolactin on RNA synthesis is mediated by PGF_{2α}. Although an effect of indomethacin unrelated to its effect on prostaglandin synthesis may

Table 2 Time-course for the PGF_{2α} stimulation of RNA synthesis in mouse mammary gland explants.

Incubation time (h)	³ H-uridine incorporation into RNA (d.p.m. per µg RNA)	
	Control	PGF _{2α}
2	280 ± 22	283 ± 13
4	281 ± 16	365 ± 19

Incubation conditions were the same as those described for Table 1 except that the final incubation time was varied. Numbers are means ± s.e. of explants from 14 flasks.

explain the abolition of the prolactin effect, this seems unlikely since indomethacin did not attenuate the effect of $\text{PGF}_{2\alpha}$ on RNA synthesis (data not shown).

Further studies (Table 2) showed that the time-course for the effect of $\text{PGF}_{2\alpha}$ on RNA synthesis did not differ from that reported for prolactin⁷. The effect of $\text{PGF}_{2\alpha}$ on RNA synthesis was apparent after a 4-h incubation but not after a 2-h incubation.

These observations therefore suggest that $\text{PGF}_{2\alpha}$ may be the 'first messenger' for the action of prolactin on RNA synthesis in the mammary gland, whereas cyclic GMP may function as the 'second messenger'. It is interesting that lactation can be initiated in rats⁸ and humans⁹ when parturition is induced by administration of $\text{PGF}_{2\alpha}$. It thus seems likely that after parturition under physiological circumstances, prolactin may contribute to the initiation of lactation by a stimulation of the production of $\text{PGF}_{2\alpha}$.

This investigation was supported by a grant from the National Institute of Child Health and Human Development. Hormones used were donated by the following: ovine prolactin (NIH P-S-9) by the National Institutes of Arthritis and Metabolic Diseases; insulin by Eli Lilly and Company; prostaglandins by the Upjohn Company; indomethacin by Merck and Co., Inc.

Endogenous protein kinase activity in nuclear RNP particles from HeLa cells

To elucidate the mechanisms which achieve and regulate the transport from the nucleus to the cytoplasm of those sequences of heterogeneous nuclear RNA (HnRNA) destined to become cytoplasmic mRNA, we have started a systematic investigation of the proteins associated with these RNA species in the form of the so-called 'RNP particles'. The general occurrence of such ribonucleoprotein complexes in eukaryotic cells is widely recognised although they have only recently been described in HeLa cells^{1,2}. The occurrence of phosphorylated proteins in rat brain nuclear particles³, together with the observation that mRNA release from adenovirus-infected KB cell nuclei *in vitro* is an ATP-dependent process⁴, has prompted a search for protein kinase activity in HeLa nuclear RNP particles. The role of protein phosphorylation in the regulation of enzyme activity is now recognised⁵ and we have observed such an activity which does not require the addition of exogenous substrates like histones. The endogenous protein substrates present in HeLa nuclear RNP particles have also been characterised.

RNP particles were spontaneously released from HeLa nuclei during incubation at 37°C (refs 1 and 6) and purified through a sucrose cushion. After incubation in the absence of added protein substrate, these particles are able to catalyse incorporation of radioactive phosphate from $\gamma\text{-}^{32}\text{P}\text{-ATP}$ into acid-insoluble form, the extent of incorporation being proportional to the amount of particles expressed as protein (Fig. 1a). This material was unambiguously identified as phosphoprotein by its insolubility in hot trichloroacetic acid, sensitivity to Pronase and resistance to ribonuclease. Cyclic AMP had no detectable

Fig. 1 Protein kinase activity in HeLa nuclear RNP particles. HeLa nuclear particles were prepared from 10^6 cells essentially as described¹. These 'native particles' were divided into two fractions. One half was kept at 0°C in 0.2 ml TM buffer (0.1 M Tris-HCl (pH 7.8), 10 mM MgCl_2) until use, whereas the other was incubated overnight in TM containing 0.5 M KCl at 0°C. This latter fraction was poured over a 3 ml sucrose cushion (20% w/v) in the same buffer and centrifuged at 55,000 r.p.m. for 4 h at 4°C in the SB405 rotor of an IEC B 60 ultracentrifuge. The pellet of 'washed particles' was resuspended in 0.2 ml TM buffer. The supernatant above the sucrose cushion (0.3 ml) was referred to as 'particles wash'. Protein determination was performed according to Lowry *et al.*⁷ using bovine serum albumin as standard. Reaction mixtures (0.1 ml) containing 2 nmol $\gamma\text{-}^{32}\text{P}\text{-ATP}$ (ref. 8) in TM buffer were incubated at 37°C for 15 min.⁹ The reaction was stopped with 10% trichloroacetic acid, the precipitates collected on glass filters and counted in a Tricarb scintillation spectrometer. *a*, Kinase activity in 'native particles'; *b*, kinase activity in 'washed particles' (○) and 'particles wash' (●).

effect on the rate or the extent of the phosphorylation reaction when assayed in the absence of theophyllin. Among the heterogeneous pattern of proteins associated with HnRNA in HeLa nuclei^{1,2}, a major species of molecular weight about 40,000 can be preferentially, although not exclusively, detached from RNP particles by 0.5 M NaCl³. Kinase activity was found to be localised exclusively in the 0.5 M KCl 'particles wash' (Fig. 1b) but not 'washed particles'. As in the case of complete particles, the reaction did not require exogenous substrate, such as histones, indicating that the 'particles wash' contains both the enzyme and its substrate. The absence of detectable activity in washed particles, however, could also reflect the complete removal of the endogenous substrate in addition to that of the enzyme itself. The fact that addition of H1 histone from calf thymus to washed particles did not significantly increase the amount of ^{32}P incorporated (not shown) renders the first possibility very unlikely unless the enzyme has such a restricted specificity as to be unable to phosphorylate any protein but its own cognate substrates. Although no kinase activity could be detected in the 'washed particles', it is apparent from the comparison of ordinates in Fig. 1a and b that the specific activity of the wash fraction is lower than that of untreated particles. This may result from either a greater enzyme stability and/or a more favourable spatial relationship with the substrates in the 'native particles' than in the soluble 'particles wash'.

We therefore characterised, using SDS-gel electrophoresis, the phosphoproteins produced *in vitro* by native particles (Fig. 2b), and by the 0.5 M KCl wash (Fig. 2d), with reference to the corresponding densitograms of stained gels (Fig. 2a and c). The protein pattern of native nuclear particles (Fig. 2a) is similar to those previously reported^{1,2}, whereas that of the 'particles wash' (Fig. 2c) shows a considerable enrichment in protein species of about 40,000 daltons in agreement with Pederson's report that 'washed particles' are preferentially depleted in this protein species². The distribution of ³²P radioactivity shows two discrete peaks corresponding to molecular weights of about 85,000 and 40,000 for both native particles and 'particles wash'. It has consistently been observed that the 85,000-dalton species is preferentially phosphorylated in the wash fraction while the reverse is true in 'native particles'. A closer association of the kinase with the 40,000-dalton species

in 'native particles' can be invoked. An additional phosphorylated species of molecular weight 26,000 has occasionally been observed and this may reflect the occasional presence in some particle preparations of an adventitiously bound protein, possibly a histone, from another nuclear compartment. This point is currently being investigated.

We have described the occurrence of protein kinase activity in the nuclear RNP particles from HeLa cells which can be selectively detached, together with its endogenous substrates, by 0.5 M KCl. A few discrete protein species seem to become phosphorylated in the reaction. While this work was being completed, a similar endogenous protein kinase activity has been reported in rat liver nuclear particles¹² which is able to phosphorylate polypeptides with molecular weights of 25,000, 36,000 and 42,000.

The main proteins released by washing the particles with 0.5 M NaCl have molecular weights of about 40,000 (Fig. 2c and ref. 2). We have recently isolated, using an affinity chromatography on poly(A)-Sephacryl column, a phosphorylated protein from HeLa cytoplasm whose size in SDS-acrylamide gels is close to the above value¹⁰. Preliminary experiments indicate that this protein fraction contains kinase activity (unpublished results).

We thank Dr J. Kruh for stimulating this work, and Dr I. Gourevich for histone.

Fig. 2 Sodium dodecyl sulphate-acrylamide gel electrophoresis of proteins from 'native particles' and 'particles wash' incubated *in vitro* with γ -³²P-ATP. Protein from 'native particles' (80 μ g) and 'particles wash' (60 μ g) were incubated in 100 μ l TM buffer in the presence of γ -³²P-ATP as described in the legend to Fig. 1. Denaturation of the samples, electrophoresis on 10% acrylamide gels containing 0.1% sodium dodecyl sulphate, staining of the gels and densitometer tracing were carried out as previously described.¹⁰ Gels were then cut into 1 mm slices and counted directly in a Packard-Tricarb scintillation spectrometer using Cerenkov radiation. Molecular weights were estimated according to Weber and Osborn¹¹, using bovine serum albumin, aldolase and human γ globulin as standards. Densitometer tracings of proteins from 'native particles' (a) and 'particles wash' (c). ³²P radioactivity incorporated into proteins from 'native particles' (b) and 'particles wash' (d).

Analysis of X-ray-induced chromosomal translocations in human and marmoset spermatogonial stem cells

ONE of the major classes of genetic damage produced by ionising radiations is heritable reciprocal translocation. In a series of earlier publications, Brewen and Preston¹⁻³ demonstrated that each of several mammalian species has its own unique sensitivity to translocation induction in peripheral leukocytes and that human and marmoset leukocytes, although approximately equal in sensitivity, were twice as sensitive as mouse leukocytes. Brewen and Preston⁴ also reported that in the Chinese hamster and the mouse, the frequency of the translocation type analysed in the peripheral leukocytes was three to four times as high as the frequency of heritable translocations produced in spermatogonial stem cells and recovered in primary spermatocytes. As the mouse is the mammal currently used as the model for estimating man's genetic risk from mutagenic exposure, Brewen and Preston's earlier observations on germ cells should be extended to include a primate and man if possible. Here we present an extension of the interspecific and somatic against germ cell comparisons.

Mature male marmosets were testicularly irradiated with acute doses of 25, 50, 100, 200, or 300 rad of 250 kV X rays. At various intervals after irradiation, depending on the X-ray dose,

bilateral castration was performed, and preparations were made by the method of Evans *et al.*⁵, as modified by Chandley (personal communication). Biopsy material was also obtained from nine men, six of whom had received testicular X-ray exposures of 78, 200, or 600 rad. Details of the irradiation regime are given by Heller and Rowley⁶. The interval between exposure and sampling varied among the individuals, because the programme had been in progress for some time before the cytological investigation was started. Preparations were made by the same procedure as that used for the marmosets. Human and marmoset diplotene-diakinesis figures were analysed for the presence of multivalent configurations (Fig. 1) which were the result of reciprocal translocations induced in spermatogonial stem cells.

The results of this meiotic analysis are presented in Table 1. Previously published data⁷ from mouse studies are also presented in Table 1 for the sake of comparison. Yields of dicentric chromosomes, calculated from the coefficients of regression curves¹, in peripheral leukocytes at the same doses are presented for each species in order that somatic against germ cell comparisons can be made.

The data indicate that, as in the case of the peripheral leukocyte studies, both man and marmoset are at least twice as sensitive to reciprocal translocation induction in spermatogonial stem cells as the mouse. The ratio of somatic cell translocations (that is, dicentrics) to germ cell translocations is approximately 2:1 in man and marmoset at X-ray doses of 100 rad and lower. This variation from the mouse data might be explained by the greater efficacy in observing reciprocal translocations in the primates because the increased chiasmata frequency in primates

Fig. 1 Examples of diplotene-diakinesis figure in marmoset and human primary spermatocytes. *a*, Normal marmoset; *b*, ring-of-IV marmoset; *c*, ring-of-VI marmoset; *d*, normal human; *e*, ring-of-IV human; *f*, ring-of-VI human.

Table 1 Frequencies of reciprocal translocations in meiotic cells and dicentrics in peripheral leukocytes following X-ray exposure to man, marmoset, and mouse

Dose (rad)	Man		Marmoset		Mouse	
	% Dicentrics	% Reciprocal translocations \pm s.e.*	% Dicentrics	% Reciprocal translocations \pm s.e.†	% Dicentrics	% Reciprocal translocations \pm s.e.‡
0	0.0	0.0	0.0	0.0	0.0	0.0
25	—	—	3.0	2.8 ± 0.7	0.9	—
50	—	—	6.7	3.3 ± 0.8	2.1	0.7 ± 0.3
78	8.0	4.0 ± 1.0	—	—	—	—
100	—	—	16.3	7.8 ± 1.1	5.5	1.5 ± 0.5
200	35.2	7.0 ± 1.3	44.6	7.5 ± 1.9	16.4	4.3 ± 0.8
300	—	—	84.9	7.0 ± 1.1	32.7	7.8 ± 1.1
600	250.0	6.1 ± 1.8	—	—	114.0	19.5 ± 1.6

* The number of cells analysed at 78, 200, and 600 rad were 371, 300, and 180, respectively.

† A total of 600 cells were analysed from four testes at each dose, except for 200 rad where 200 from two testes were analysed.

‡ 600 cells were analysed at each dose.

will give a higher probability of a multivalent association being maintained at diplotene-diakinesis. The dose-response characteristics of translocation induction in the germ cells of man and marmoset are similar to those of the mouse. For all three, a peak yield is reached with an apparent decrease at higher doses. This peak yield, however, occurs at approximately 100 rad in the primates whereas it occurs at 500–600 rad in the mouse.

Using the translocation frequencies observed at doses of 100 rad and lower, the mean rate of reciprocal translocation induction in man and marmoset is 7.7×10^{-4} translocations per cell per rad. Using the data of Ford *et al.*¹⁸ on the rate of transmission of cytologically scored translocations to F_1 offspring of irradiated male mice as the lower limit of transmission (that is 1:8), and the expected frequency of transmission of 1:4 as the upper limit, a calculation of transmissible reciprocal translocations per gamete per rad can be made. This value is 0.96×10^{-4} – 1.93×10^{-4} translocations per gamete per rad for acute X-ray exposures.

Jacobs⁹ and Hamerton¹⁰ have summarised the data on the frequency of translocations in live births. The figures are: 0.06% reciprocal translocations, 0.08% Robertsonian translocation, and 0.03% unbalanced translocations. Jacobs *et al.*¹¹ have estimated that the spontaneous rate of viable translocations per gamete per generation is about 4×10^{-4} , of which 2.8×10^{-4} are balanced and 1.2×10^{-4} are unbalanced. This estimate is a minimum as not all translocations can be detected by somatic cell chromosome analysis. So, if it is assumed that the measured spontaneous rate is between 0.25 and 1.00 of the true spontaneous rate, the estimated doubling dose for the induction of reciprocal translocations by acute X rays is 2–16 rad.

In estimating a doubling dose for protracted (that is, chronic) exposures, one precaution must be taken. The experiments to date, using low dose rate irradiation, have been done with large total doses where the dose rate effect is maximised. In making risk estimates the principle concern is for low dose levels where, according to theory and experimental evidence, the dose rate effect for low LET radiations is minimal because of the small contribution by the two-track component. Thus a conservative estimate of a doubling dose for low-dose chronic X-ray exposure might be expected to be the same as for acute low doses with a maximum of 4–30 rad.

This research was sponsored by the United States Atomic Energy Commission under contract with the Union Carbide Corporation. We thank Dr C. G. Heller and Ms Mavis Rowley for help in obtaining biopsy material from the testicular irradiated male volunteers. Dr Gengozian was supported by United States Public Health Service Grant from the National Institutes of Health.

Estimation of accessibility of DNA in chromatin from fluorescence measurements of electronic excitation energy transfer

EUKARYOTIC DNA is complexed with proteins which influence its conformation, stability and function^{1,2}. Attempts to correlate the chemical and biological properties of chromatin have focused on the coverage of DNA by chromosomal proteins³⁻⁸. As much as 50% of the DNA in chromatin is accessible to precipitants (such as basic dyes or polylysine)³⁻⁶ or to limiting nucleolytic digestion^{3,4,6-8}, suggesting a model of segmental DNA accessibility in chromatin resembling a frayed telephone wire. Digestion extensively alters chromatin structure, however, and the results of experiments involving precipitation or digestion may be influenced by processes associated with the aggregation phenomena serving as experimental endpoints. We have used an alternative approach to characterise DNA accessibility in chromatin using the transfer of electronic excitation energy between pairs of fluorescent dyes bound to chromatin at low ratios of dye to phosphate. The results suggest that at least one-third of the DNA in chromatin retains a high affinity for basic dyes. The exclusion of dyes or other molecules⁹ from portions of chromatin may, however, depend on the conformation of chromatin as well as on the protein-DNA stoichiometry.

The dyes quinacrine, acridine orange and 33258 Hoechst were chosen as energy donors. All three bind tightly to DNA and chromatin, exhibiting a fluorescence emission spectrum that extensively overlaps the absorption spectrum of the energy acceptor used, ethidium bromide. Following excitation of the donor, energy will be transferred with a high probability to ethidium molecules bound within a critical distance (approximately 25-35 Å) of the donor. Energy transfer efficiency decreases sharply with donor-acceptor separations above this value. The critical donor-acceptor distance for 50% efficient energy transfer, R_0 , determined by individual spectroscopic parameters and relative dye orientations^{10,11}, differs little between DNA and chromatin complexes with any particular donor-acceptor pair, although it varies somewhat between the three donor-acceptor pairs. The relative efficiency of energy transfer between fixed amounts of donor and acceptor bound to either DNA or chromatin depends on the probability that an acceptor molecule will bind within R_0 of the donor and thus, to a first approximation, this energy transfer varies inversely with the acceptor binding space. Hence it provides an estimate of DNA accessibility in chromatin.

Energy transfer in any particular region of chromatin (of length $\gg R_0$) should be proportional to the product of the binding affinities of the donor and acceptor to this segment and will thus reflect the correlation between donor and acceptor binding. Results averaged over many regions will also be weighted according to variations in energy donor fluorescence efficiency. For an accurate estimate of the acceptor binding space, the acceptor should bind to all regions accessible to the donor and the acceptor should not bind preferentially to particular regions of DNA. Quinacrine and ethidium bromide

seem to constitute a suitable donor-acceptor pair, since they both bind to DNA by intercalation in a mutually competitive manner with little base-composition specificity¹²⁻¹⁵.

If ethidium bromide is added to a quinacrine-DNA complex, quinacrine fluorescence is quenched by energy transfer to nearby ethidium molecules, which concomitantly exhibit sensitised fluorescence. At low donor and acceptor saturations, under conditions such that virtually all dye molecules are bound, the donor fluorescence intensity (F) varies inversely with the amount of added acceptor (Fig. 1). The amount of ethidium bromide necessary for a 50% reduction in donor fluorescence (ethidium bromide)₅₀ increases in proportion to the total accessible DNA phosphate concentration (Fig. 2). Quenching of the fluorescence of quinacrine bound to chromatin occurs at about one-third of the amount of added ethidium bromide needed for a comparable effect on quinacrine-DNA complexes (Fig. 2). Direct measurements of quinacrine binding¹⁵ indicate that calf thymus chromatin also possesses about one-third the number of quinacrine binding sites found in an equal amount of DNA, consistent with the existence of an extensive overlap between quinacrine and ethidium bromide binding spaces in chromatin.

Fig. 1 Energy-transfer quenching of quinacrine fluorescence by ethidium in complexes with calf thymus DNA. The fluorescence of a 2-ml sample of a 0.7×10^{-6} M solution of quinacrine complexed with 2×10^{-4} M calf thymus DNA (in 0.01 M NaCl, 0.005M HEPES, pH 7) was measured after successive 20- μ l additions of a 1×10^{-4} solution of ethidium bromide. Excitation was at 420 nm. Quinacrine fluorescence (F), measured at 493 nm, was corrected for dilution by the ethidium bromide solution and for a very small amount of quenching due to the trivial process of fluorescence and reabsorption. F_0 is the initial fluorescence in the absence of added ethidium. The ratio of F_0/F is plotted against the amount of added ethidium bromide.

Estimates of DNA accessibility in chromatin range from 28%, with acridine orange as the donor to 60%, with the bisbenzimidazole dye 33258 Hoechst (Table 1). This range may reflect variations both in the correlation of donor and acceptor binding distributions and in the quantum yield of donor molecules bound to different DNA sequences. Differences in the mode of binding of donor molecules might also be important. Quinacrine and acridine orange intercalate between DNA bases¹⁴, while 33258 Hoechst, which is a large bisbenzimidazole dye, may occupy one of the grooves of the DNA double helix¹⁷. Preliminary measurements indicate that approximately half of the sites in DNA for 33258 Hoechst binding are available in calf thymus chromatin. If some of these sites are inaccessible to ethidium bromide, the above value of 60% for DNA accessibility in chromatin obtained with 33258 Hoechst as energy donor would be an overestimate. The figures for DNA availability reported here bracket results from experiments involving polylysine or direct measurements of dye binding³⁻⁸. Similar estimates for DNA accessibility in chromatin, using

Fig. 2 Energy transfer titration of available phosphate in calf thymus DNA or chromatin. The amount of ethidium bromide at which quinacrine fluorescence is reduced 50%, obtained from data such as those of Fig. 1, is plotted against the amount of calf thymus DNA (○) or calf thymus chromatin (●) present in solution. Data were obtained at ratios of ethidium to phosphate of 0.025 or less. Calf thymus chromatin was prepared by extracting a crude nuclear pellet with 0.024 M EDTA, 0.075 M NaCl, pH 8.0¹⁶, swelling in 0.01 M NaCl, 0.005 M HEPES, pH 7.0, sedimenting through 1.7 M sucrose, and shearing at high speed.

measurements of energy transfer between other dye combinations, have been obtained by Gursky *et al.*¹⁸.

The differences in energy transfer between dye molecules bound to DNA and chromatin can arise if proteins simply exclude dye from some regions without affecting binding in

others¹⁹. They can also occur, however, if donor and acceptor molecules are statistically crowded into limited regions by correlated alterations in binding affinities. To determine whether the higher order structure of chromatin has such an influence on dye binding, energy transfer measurements were made on samples of chromatin either dissolved in 5 M urea or digested briefly with trypsin. Both treatments have been reported to disrupt chromatin structure, as determined principally by circular dichroic and hydrodynamic measurements, with at most a moderate dissociation of protein^{20,21}. The energy transfer between dyes bound to chromatin in 5 M urea was virtually identical to that with DNA (Table 1). Protein dissociation in 5 M urea, estimated by sucrose gradient centrifugation, was negligible. Following trypsin treatment which released less than 30% of the protein from DNA, the apparent accessibility of DNA in the chromatin increased to about three-quarters of that of free DNA (Table 1). Both urea and trypsin treatments increase the apparent accessibility of chromatin to ethidium bromide more than they alter the ratio of protein to DNA. These results are consistent with the idea that reaction of dyes with chromatin depends on chromatin conformation as well as on the literal coverage of chromosomal DNA by protein. It cannot, however, be excluded that a change in the mode of interaction of the residual protein with DNA contributed to our observations.

Table 1 Estimation of DNA exposure in chromatin using electronic excitation energy transfer

Energy donor	Polymer	(Ethidium bromide) ₅₀ /Pi [‡]	DNA accessibility§
Quinacrine	DNA	0.044	1.00
	Chromatin	0.016	0.36
	Trypsinised*	0.036	0.83
	Chromatin		
Acridine orange	DNA	0.027	1.00
	Chromatin	0.008	0.28
	Trypsinised*	0.019	0.70
	Chromatin		
	DNA in 5 M urea†	0.024	1.00
33258 Hoechst	Chromatin in 5 M urea†	0.025	1.03
	DNA	0.041	1.00
	Chromatin	0.025	0.60
	Trypsinised*	0.032	0.78
	Chromatin		
	DNA in 5 M urea†	0.039	1.00
	Chromatin in 5 M urea†	0.040	1.03

All measurements were made in 0.01 M NaCl, 0.005 M HEPES, pH 7.0, 21–22°C. DNA and chromatin concentrations were between 1×10^{-4} and 4×10^{-4} M. Energy donor concentrations were between 1×10^{-7} and 7×10^{-7} M. 33258 Hoechst (2-(2-(4-hydroxyphenyl)-6-benzimidazolyl)-6-(1-methyl-4-piperazyl)-(benzimidazol-2HCl)) was a gift of Dr H. Loewe, Hoechst AG, Frankfurt.

* Chromatin was treated with 8U of tosylphenylchloroketone-treated trypsin (Worthington) per μ mol chromatin DNA phosphate for 2 h at 22°C before measurements were made.

† Urea was added to a final concentration of 5 M in 0.01 M NaCl, 0.005 M HEPES, pH 7.0. Addition of ethidium bromide to DNA plus quinacrine in this solvent did not quench quinacrine fluorescence.

‡ (Ethidium bromide)₅₀/Pi is the estimated ethidium bromide/phosphate saturation of DNA or chromatin at which donor fluorescence is quenched by 50%. In most experiments, this was determined by fitting data like those of Fig. 1 to a straight line after the addition of 8–10 nmol of ethidium bromide. When acridine orange was the energy donor, however, such plots consistently exhibited upward concavity, and initial slopes were estimated using least squares fits of data after the addition of only approximately 5 nmol of ethidium bromide.

§ DNA accessibility is calculated as the ratio of (ethidium bromide)₅₀/Pi in chromatin relative to that with DNA under the same conditions.

Concanavalin A cap formation on polymorphonuclear leukocytes of normal and beige (Chediak-Higashi) mice

TREATMENT of a variety of cell types with concanavalin A (con A) leads to the aggregation of the lectin into one region or pole of the cell, forming a so-called cap. Not all cells cap (erythrocytes and normal cultured fibroblasts do not). Cells which do cap can be distinguished as (a) lymphocytes¹ and rabbit exudate polymorphonuclear leukocytes (PMN) (our data) that cap directly when incubated with low concentrations of con A at 37°C, and (b) cells exemplified by SV40-transformed fibroblasts² and lymphocytes incubated with high (more than $5 \mu\text{g ml}^{-1}$) concentrations of con A¹ that cap only after incubation with colchicine which

Cell monolayers were preincubated at 37° C in modified Hanks medium containing 5 mM glucose plus the drugs indicated. After 30 min, fresh glucose-free medium containing FITC-con A ($5 \mu\text{g ml}^{-1}$) plus the same concentration of drugs was added and incubation was continued for 15 min. Cells were rinsed and either fixed immediately or postincubated for 20 min at 37° C with medium containing drugs before fixation. Results were obtained by examining 100 cells at random and assigning each cell to one of the 3 labelling categories (see text) according to the distribution of fluorescence. All experiments were done using blood from one normal and one CH mouse (3–5 weeks old) and with the same solutions of drugs and FITC-con A. The data in lines 1–13 are results from one representative experiment and those in lines 14–17 from a separate experiment. Some variation was observed between blood obtained from different animals, but qualitatively all effects were the same. The range of capping in the absence of drugs varied between 8 and 19% in 11 normal mice and between 36 and 58% in 11 CH mice. In all experiments, about 20% of cells showed a patchy labelling with FITC-con A.

disrupts microtubules (MT). These differences between cell types are not understood.

We report here that peripheral blood PMN from normal mice (C57/6J $+/+$ and $+/bg$) do not cap with con A except after colchicine treatment. This colchicine-induced capping is antagonised by cyclic GMP and agents that stimulate its production. In addition, we show that PMN from beige or Chediak-Higashi (CH) mice (C57/6J bg/bg) cap spontaneously with con A and that capping on these cells is also blocked by cyclic GMP. These results suggest a role for cyclic GMP in the regulation of surface phenomena that depend on MT and form the basis for a new hypothesis to explain the pathogenesis of the CH syndrome.

Mouse peripheral blood PMN were obtained as before³ and suspended in modified Hanks medium containing 5 mM glucose. Fluorescein-conjugated con A was prepared by incubating fluorescein isothiocyanate (FITC, Sigma) at a concentration of 0.05 mg mg^{-1} con A for 1 h at 0° C in the presence of 100 mM glucose (to protect the binding site) and phosphate buffer, pH 7.5, and purifying the product after dialysis by affinity chromatography on Sephadex G-50². Monolayers of cells were allowed to form on glass coverslips⁴ and labelled at 37° C with $5 \mu\text{g ml}^{-1}$ con A for 15 min, then rinsed in modified Hanks solution, fixed in 2% paraformaldehyde at 37° C for 10 min and wet mounted. The labelled cells were observed by combined phase-fluorescence using a Zeiss epifluorator with an FITC interference filter, 450 dichroic mirror, 53 barrier filter, and a 100 neofluar phase objective.

The observed fluorescence was categorised according to three labelling patterns: (1) random or diffuse; (2) cap—either a polar shell of fluorescence or a more concentrated knob or protrusion; (3) patchy—clumped aggregates—often perinuclear, or occasionally peripheral, or as larger more central irregular clusters. Examples of each labelling pattern can be seen in Fig. 1. Treatment of labelled cells with 50 mM α -methyl mannoside removed labelling of the first two patterns (diffuse or cap). Aggregates were not removed, however, indicating that the third or patchy pattern corresponds to endocytosed con A that is inaccessible to the

sugar. This endocytosed con A shows a superficial resemblance to surface (centrally located) caps. The development of the observed patterns seems to follow the sequence 1 to 2 to 3, or 1 to 3 directly (that is, endocytosis without an intermediate cap stage).

Table 1 is a summary of the patterns of fluorescence distribution observed with peripheral blood PMN from normal and CH mice. There was a striking increase in the proportion of capped cells and a corresponding decrease in the proportion of cells showing a random distribution of fluorescence in CH-PMN as compared with PMN from homozygous ($+/+$) or heterozygous ($+/bg$) normal mice (line 1). This difference is illustrated in Fig. 1a and b. Preincubation of monolayers for 30 min with colchicine promoted cap formation in normal PMN but had little additional effect on the extreme degree of capping in CH-PMN (lines 1 and 2). After colchicine treatment the degree of capping in normal PMN was very similar to that in untreated CH-PMN (compare Fig. 1b with c). Lumicolchicine (line 3), a photochemical derivative of colchicine that does not affect microtubules, did not affect capping.

The effects of cyclic nucleotides on capping were investigated because these compounds have been implicated in regulation of colchicine-sensitive (microtubular) functions in several systems. Thus both 3',5'-cyclic adenosine monophosphate (cyclic AMP) and compounds which increase its intracellular concentration, and colchicine, reduce antigen-induced histamine release⁵ and endocytosis-induced release of lysosomal enzymes⁶ from leukocytes. In contrast, both cyclic GMP and agents that elevate its intracellular concentration and deuterium oxide which favours MT assembly, augment histamine and enzyme release in the same *in vitro* models.

Our data show that preincubation of cell monolayers for 30 min with cyclic GMP (line 4) as well as carbamylcholine (carbachol; line 5) and phorbol myristate acetate (PMA, line 6) at concentrations which elevate cyclic GMP levels in PMN^{6,7} caused a marked reduction in capping on CH-PMN and slightly reduced capping on normal PMN. In fact, the degree of capping on CH-PMN after addition of

cyclic GMP was virtually identical to the untreated normal PMN (compare Fig. 1a with d). This effect was chemically specific for the cyclic guanine nucleotide since the potential products of its degradation, guanine (line 7), guanosine (line 8) and 5'-GMP (line 9) did not affect capping. In addition, cyclic AMP (line 10) had no significant effect on cap formation on either CH or normal cells.

When normal cells were preincubated with cyclic GMP (line 11), carbachol (line 12) or PMA (line 13) simultaneously with colchicine, the characteristic stimulation of capping by colchicine (compare line 2) did not occur (Fig. 1e and f). Thus cyclic GMP and compounds which increase intracellular concentrations of this nucleotide antagonised the extensive capping of con A that occurred on both untreated CH-PMN and colchicine-treated normal PMN. The effect of cyclic GMP was readily reversible, indicating that the observed effects occurred without loss of cell viability. Cap formation on normal PMN was enhanced by incubation with colchicine both before (line 2) and after (line 15) labelling with FITC-con A and was antagonised by the simultaneous presence of cyclic GMP in both cases (lines 11 and 16). Cells incubated with cyclic GMP before labelling and with colchicine after labelling (line 17), however, showed a similar increase in con A capping to cells exposed to colchicine alone.

Two mechanisms have been suggested to explain the effect of colchicine on cap formation. According to one hypothesis¹, high concentrations of con A induce an association between intracellular colchicine-binding proteins (presumably MT) and the cell surface that inhibits the lateral migration of bound ligands within the membrane, and colchicine, by virtue of its effects on MT, permits

this movement of surface constituents to resume. A second hypothesis^{8,9} is that cell or membrane movements are required to aggregate lectin-receptor complexes: con A immobilises the cell and colchicine promotes capping only under conditions in which it can restore cell movement. We have shown that cyclic GMP, which stimulates both random and directed (chemotactic) cell movement⁷ does not enhance capping by con A on normal PMN. Further, cyclic GMP antagonises the increase in capping that is induced by colchicine in normal PMN. These observations are consistent with the first hypothesis, in which capping is independent of cell movement.

We have also shown increased capping by con A on PMN from CH mouse. This mutant^{10,11}, like mutants of mink¹² and cattle¹³, is a homologue of the Chediak-Higashi syndrome of man¹⁴, a rare autosomal recessive disorder characterised by partial albinism, the presence of giant granules in most granule-containing cells, impaired leukocyte chemotaxis and defective lysosomal degranulation. The current view of the CH syndrome is that subcellular granule membranes may be defective in structure or function^{15,16}. The apparent increase in the mobility of lectin-receptor complexes on the plasma membranes of PMN from CH mice, which results in extensive cap formation, indicates that this view should now be extended to include other membranes. Furthermore, membranes of CH-PMN behave like membranes of colchicine-treated normal cells in which MT are depolymerised, in terms of their capping response to con A. This could show that the fundamental defect may be an abnormality in MT polymerisation and/or in the interaction between membranes and MT.

The intracellular mechanisms that regulate MT assembly are not yet understood. Our observation, however, that cyclic GMP antagonises the increased con A capping due to colchicine in normal PMN suggests that the cyclic nucleotide may promote MT polymerisation. Reports that cyclic GMP levels increase in lymphocytes¹⁷ and human PMN (J.M.O. and R.B.Z., unpublished) after binding of con A and that the number of MT seen by electron microscopy in human PMN is increased by agents that elevate cyclic GMP¹⁸ are consistent with this proposal. We suggest that in normal PMN binding of con A may elevate cyclic GMP and thereby promote MT assembly. In CH-PMN the generation of cyclic GMP in response to con A may be inappropriately low.

Fig. 1 The distribution of FITC-con A on peripheral blood PMN from normal and beige (CH) mice. *a*, Normal PMN: the diffuse labelling pattern predominates. *b*, CH-PMN: most cells are capped. *c*, Normal PMN incubated with $1 \mu\text{M}$ colchicine: the degree of capping is similar to CH-PMN without colchicine. In one cell the cap has begun to be internalised and fluorescence is seen in a clumpy aggregate. *d*, CH-PMN incubated with $0.5 \times 10^{-4} \text{M}$ cyclic GMP: the labelling pattern is diffuse as in the normal PMN. *e*, Normal PMN incubated with both cyclic GMP and colchicine: cyclic GMP antagonises the increased cap formation seen with colchicine alone. *f*, CH-PMN incubated with both cyclic GMP and colchicine: most of the label is distributed randomly. One cell shows a central cluster of fluorescence that resembles a central cap. This fluorescence cannot, however, be removed by α -methylmannoside and so it most likely represents internalised con A.

Specific IgE antibodies in immune adherence of normal macrophages to *Schistosoma mansoni* schistosomules

PARASITIC helminths characteristically provoke high levels of IgE antibodies in man and similar reagin-type antibodies in animals. But it has not been demonstrated conclusively that these antibodies have a protective role.

When they are incubated in the serum of Fisher rats immune to *Schistosoma mansoni*, the peritoneal adherent cells of normal inbred Fisher rats are strongly adherent to *S. mansoni* schistosomules maintained *in vitro*^{1,2}. Electron microscopy has shown that the adherent cells are macrophages. Here we report experiments which indicate that the factors in immune serum responsible for the macrophage adhesion are specific anti-schistosome IgE antibodies.

Serum samples were obtained by bleeding infected Fisher rats at various intervals after exposure to 400 cercariae of *S. mansoni* (group 1). Uninfected Fisher rats were used as a control (group 2). A highly significant correlation was obtained between the percentage of macrophage-coated schistosomules and the time elapsed since infection ($r=0.562$; $n=80$; $P<0.001$).

After infection for 30 d, the mean percentage of macrophage-coated schistosomules was significantly higher in group 1 than in group 2 (Fig. 1). After 50 d, the mean percentage of macrophage-coated schistosomules was 88.4% (s.d. 9.4; $n=8$) compared with a value for the uninfected control sera of 29.8% (s.d. 23.1; $n=6$; $P<0.001$). The control values could be reduced to a mean of 10% if sera from uninfected germ-free rats were used (A.C., J.-P.D., M.C., and H.B., unpublished).

Adherence of immune serum-incubated macrophages was inhibited when the serum was heated at 56°C for 3 h and

Fig. 1 Relationship between the adherence of serum-incubated macrophages and the period of infection of rats by *S. mansoni* cercariae. Normal syngenic Fisher rat macrophages were collected by peritoneal washing with Eagle's MEM and plated in Falcon dishes. Non-adherent cells were washed off after 3 h incubation. Adherent population was incubated in MEM containing 20% of either immune (group 1) or normal (group 2) rat serum. At least five replicates in each group were performed. Approximately 200 *S. mansoni* schistosomules recovered according to the technique described by Clegg and Smithers³, were added and adherence of macrophages was estimated after 3 h contact under an inverted phase contrast microscope. More than 30 adherent macrophages to one schistosomule was considered to be significant and the percentage of embedded schistosomules was calculated. ●, Group 1; ◆, group 2; s.d. are indicated by vertical lines through points. Statistical analysis (Student's *t* test and Wilcoxon two samples test) showed highly significant ($P<0.01$) differences between the two groups.

Fig. 2 Thermolability of serum factor involved in macrophage adherence to *S. mansoni* schistosomules, as estimated by heating infected rat serum 30–180 min at 56°C before incubation with normal macrophages and schistosomules. Results are expressed as percentage of schistosomules with adherent macrophages.

was not restored by addition of guinea pig fresh serum. It was therefore assumed that a thermolabile factor could be responsible for macrophage adherence.

Absorption of rat immune sera by *S. mansoni* soluble antigens before incubation was shown to decrease significantly the adherence of the macrophage to the schistosomules, indicating that the factor was probably a thermolabile antibody. To assess this hypothesis, various experiments were devised.

The thermolability of the serum factor was confirmed by estimating the percentage of macrophage-coated schistosomules after incubation with sera heated for periods of 30–180 min (Fig. 2). Absorption of rat *S. mansoni* immune sera by increased quantities of goat anti-rat IgE serum, specific for ϵ chain, or $F(ab')_2$ of the same antiserum⁴, led

Table 1 Comparison of immune adherence of normal macrophages incubated in infected-rat serum before and after absorption with anti-rat IgE immunosorbent

Serum	% Schistosomules with adherent macrophages (mean \pm s.d.)	Significance	IgE level (μ g ml ⁻¹) (mean \pm s.d.)

Absorbed	4.80 \pm 3.56	$t = 25.455$ $P < 0.0001$	1.31 \pm 0.32
Unabsorbed	92.25 \pm 5.06	$C_1 = 3.26$ $P \leq 0.01$	10.20 \pm 0.44
Day 68			
Absorbed	12.2 \pm 9.70	$t = 29.371$ $P < 0.0001$	0.01 \pm 0.40

The solid phase anti-IgE was prepared with goat-anti-rat IgE $F(ab')_2$ (ϵ specific) covalently linked to cyanogen bromide activated Sepharose. The rat serum was absorbed out by passage through the column, concentrated to the original volume and incubated with the normal rat macrophages. Means and s.d. of the percentages of coated schistosomules were calculated. Serum IgE determination was carried out by a radio-immunoassay; radioactivity bound was precipitated by 33% ammonium sulphate⁵.

to a progressive decrease of the macrophage adherence (Fig. 3).

Similar experiments with anti-rat IgG (IgG₁, IgG_{2a}, IgG_{2b}), IgM and IgA goat serum⁵ did not exhibit any significant decrease.

To avoid possible interference by soluble IgE-anti-IgE complexes and excess of anti-IgE antibodies, the same absorption experiment was carried out in solid phase using goat IgG anti-rat IgE linked to Cyanogen Bromide-activated Sepharose 3B. In these experimental conditions, a highly significant decrease of macrophage-coated schistosomules was observed (Table 1); the disappearance of IgE was controlled by radio-immunoassay.

The involvement of specific IgE antibodies in the immune adherence of normal macrophages to *S. mansoni* schistosomules could therefore be inferred. Further controls of specificity were performed with IgE myeloma serum (IR 162) (ref. 7) and with sera containing unrelated reaginic antibodies: anti-ragweed, anti-ovalbumin, anti-BGG-DNP and anti-*Nippostrongylus brasiliensis* with respective homologous PCA titres of 1:512, 1:256, 1:512, and 1:512, according to the technique of Jarrett and Ferguson⁸. None of these sera elicited any significant immune adherence of macrophages to schistosomules.

To investigate the mechanism of action of IgE in immune adherence, the possibility of nonspecific binding of IgE molecules on the macrophage surface was considered. Three different techniques were used. Rosette formation was obtained when normal rat macrophages incubated with rat IgE myeloma protein were put into contact with specific anti-rat IgE linked by glutaraldehyde on group O, rhesus negative, human red cells. Similar results were obtained when macrophages were incubated in serum from rats infected with *S. mansoni*.

Macrophages incubated with these immune rat sera demonstrated a fluorescent surface staining with goat serum anti-rat IgE revealed by anti-goat fluorescein-labelled globulins. No staining was obtained when the anti-*S. mansoni* rat serum was previously heated (56°C for 3 h) or absorbed by F(ab')₂ anti-rat IgE. The binding of IgE to the macrophage surfaces was confirmed by the use of peroxidase-labelled IgG anti-rat IgE and an ultrastructural study.

It seemed, therefore, that the nonspecific binding of IgE on rat macrophages resembles the cytophilic binding of some immunoglobulin classes in man and mouse^{9,10}. In our model the immune-adherence of the macrophage to schistosomules therefore seems to be the result on the one hand, of the specificity of IgE antibody against the parasite and, on the other hand, of a nonspecific binding on the macrophage surface, probably by the constant part of the IgE molecule.

Preliminary observations have indicated that the immune adherence of macrophages described here may have some importance in the killing of *S. mansoni* schistosomules *in vitro* methods¹¹, is highly accelerated if specific IgE antibodies for *S. mansoni* schistosomules, as studied by *in vitro* methods¹¹, is highly accelerated if specific IgE mediated adherence of normal macrophages occurs at the same time. Implications of these observations might be considered at two levels.

In the rat, reaginic antibodies were reported and their possible significance in *S. mansoni* infection considered^{12,13}. Our present observations bring an indication of a positive function of IgE antibodies in immunity to schistosomes in the rat.

Increased levels of IgE have been reported for a number of helminth infections in man¹⁴ and specific human IgE antibodies against schistosomes have now been demonstrated (J.-P.D., *et al.*, unpublished). It is reasonable then to consider the possible role of IgE-mediated macrophage adherence in schistosomiasis and other helminthoses of man.

To our knowledge, this is the first time that IgE antibodies

Fig. 3 Effect of absorption by increasing quantities of anti-rat IgE on adherence of incubated macrophages to *S. mansoni* schistosomules. A pool of group 1 rat sera was incubated with different anti-IgE concentrations (mg ml⁻¹), 2 h at 37°C, overnight at 4°C and centrifuged. Macrophages were incubated in supernatants. Δ, Absorption by goat IgG anti-rat IgE (ε specific); ■, absorption by F(ab')₂ prepared from goat IgG anti-rat IgE; ●, control experiment with F(ab')₂ prepared from normal goat IgG.

have been implicated in macrophage adherence reactions and the phenomenon should be investigated in other situations where specific IgE antibodies are involved. In any event, our experiments indicate that specific IgE anti-schistosome antibodies may have a central role in the immunity of the rat to this parasite, and are not merely concerned in the concurrent development of immediate hypersensitivity.

T-cell response to polyvinyl pyrrolidone is linked to maturity of B cells

HUMORAL antibody responses differ in their thymus dependency. Some antigens such as heterologous proteins¹, heterologous erythrocytes¹ and transplantation antigens² show a pronounced requirement for T helper cells, whereas other antigens such as bacterial polysaccharides^{3,4}, polymerised flagellin⁵ and certain synthetic polymers^{4,6} can induce a humoral antibody in the B lymphocytes in the absence of T helper cells. It has been suggested that the thymus-independent antigens are able to trigger the B cells directly because of their polymeric structure with repeating antigenic determinants⁷, because of their mitogenic properties for B cells⁸, or because they have the capacity to activate complement by means of an alternative pathway thus providing the C3 receptor-bearing B cells with an extra, activating signal⁹. It has also been proposed that thymus independency is only a relative, quantitative phenomenon and that some antigens seem thymus-independent since they need only extremely few T cells for interaction and triggering of the B cells¹⁰. It has also been demonstrated that thymus-independent antigens are slowly metabolised and non-degradable in the body, in contrast to the thymus-dependent ones⁶. The significance of this last observation is not known. We report some properties of the humoral antibody responses to polyvinyl pyrrolidone in mice. The thymus dependency of this response⁶ is shown to be a function of the stage of maturation of the B lymphocytes.

Inbred mice of (A/Sn×C57BL)F₁ genotype 8–12 months old were used as recipients in cell transfer experiments; animals at ages indicated below were used as cell donors. Immunisation with polyvinyl pyrrolidone (PVP; molecular weight 360,000) was carried out as previously described¹ and serum antibody was determined by a haemolysis of PVP-labelled erythrocytes¹. Preparation of cell suspensions and irradiation of mice was as previously described¹.

Spleen cells from adult mice (2 months old) and young mice (2 weeks old) were compared with regard to their capacity to mount a humoral antibody response to PVP after transfer to lethally irradiated recipient mice. Table 1 shows that the adult spleen cells were able to produce antibody to this antigen, and that the addition of normal adult thymus cells markedly suppressed the antibody response. In contrast, we found that the young spleen cells produced only small amounts of antibody by themselves, the antibody response being enhanced by the addition of thymus cells from normal adult mice. The effects observed on the antibody production in the PVP system were the result of T cells residing in the cortisone-resistant part of the thymus,

Table 1 Helper or suppressor effect of thymus cells exerted on young or adult spleen B cells in their response to PVP

Spleen	Thymus*	Antibody response†
2 months, 2×10^7	—	3.9 ± 0.5
2 months, 2×10^7	10^7	1.8 ± 0.5
2 weeks, 2×10^7	—	2.2 ± 0.5
2 weeks, 2×10^7	10^7	4.1 ± 0.3

*Normal, 2 month old mice were used as thymus cell donors.

†Humoral antibody titre (\log_2) 2 weeks after lethal irradiation with 750 rad and intravenous infusion of cells together with 0.1 μ g PVP mixed with the cells. Each figure represents the mean from 18 animals \pm s.e.m.

Table 2 Helper and suppressor effects of thymus cells. A comparison between thymus cells from normal, immune and tolerant animals

Thymus	Antibody titre*	
	Adult spleen	Young spleen
Normal	1.2 ± 1.2	4.5 ± 0.3
Immune†	1.9 ± 0.7	3.3 ± 0.4
Tolerant‡	5.6 ± 0.2	1.8 ± 0.9
No thymus cells given	5.6 ± 0.3	1.8 ± 0.8

*Humoral antibody titre (\log_2) in lethally irradiated mice 2 weeks after 750 rad together with intravenous infusion of the indicated cells with 0.1 μ g PVP. Each figure is the mean of five to six animals \pm s.e. Animals had received 2×10^7 spleen cells, young or adult, either alone (as in the bottom group), or together with normal, immune or tolerant thymus cells in a dose of 10^7 .

†Immune thymus cell donors had received 0.1 μ g PVP 1 month earlier as an intraperitoneal injection.

‡Tolerant thymus cell donors had received 1,000 μ g PVP intraperitoneally 1 month earlier.

as the activity of the thymus cells was not affected by passage over anti-Ig columns, and the remaining thymus cells after cortisone treatment of the donor mice were still active (B. A. and H. B., unpublished). Thymus cells treated with mitomycin C were inactive, indicating that living T cells were needed for the effects (B. A. and H. B., unpublished). Comparing the spleen B cells from young and adult mice we found the same percentage (50–60%) of cells bearing Ig on their surface but the young spleen cells had only 2–17% C3 receptor-bearing cells compared to 21–56% in the adult spleens. This possibly indicates a role for the C3 receptor in determining thymus dependency. Depletion

Table 3 Maturing B cells from the bone marrow can be helped in anti-PVP antibody response by specifically immune thymus cells

Bone marrow	Thymus*	Antibody titre†
2×10^7	—	0.2 ± 0.2
2×10^7	10^7 normal	1.2 ± 1.2
2×10^7	10^7 tolerant	1.3 ± 0.6
2×10^7	10^7 immune	4.6 ± 0.4

*Normal, tolerant and immune thymus had received the same treatment as corresponding cell donor mice in Table 2.

†Humoral antibody titres in lethally irradiated mice (750 rad) receiving the indicated cells intravenously together with 0.1 μ g PVP. Animals were bled 11 days after irradiation and cell transfer. Each group consisted of five to ten mice.

of C3-bearing cells by EAC columns¹¹ or EAC rosette sedimentation¹² and further studies on the thymus dependency in the depleted populations may provide the answer.

The effects of thymus cells on the humoral antibody response to PVP could be specific, mediated by T lymphocytes recognising antigenic determinants on the PVP molecules and acting as specific helper or suppressor cells. The effects of the thymus cells could, however, also be nonspecific, mediated, for example, by the release of factors inhibiting or stimulating the rate of proliferation and/or maturation of the B cells. To discriminate between these possibilities, the activities of thymus cells from normal, immune and tolerant donor mice were compared. Table 2 shows that pretreatment of the thymus donor mice with high doses of PVP, capable of producing tolerance, abolishes the suppressing and the helping activities of the thymus cells, whereas normal and immune thymus cells exerted both suppressing and helping activities. Table 3 shows that immune thymus cells actually perform better in one respect

than normal and tolerant thymus cells, namely in their capacity to act as helper cells for maturing B cells early after lethal irradiation and bone marrow reconstitution.

Table 1 shows that, when 2×10^7 spleen cells and 10^7 thymus cells are given, young spleen cells are stimulated and adult spleen cells are suppressed in their anti-PVP response. We point out, however, that these effects are observed only at certain critical ratios between spleen cells and thymus cells. Table 4 shows that the suppressing effect of thymus cells is not present when lower or higher doses of thymus cells than 10^7 are used to modify the response of 2×10^7 adult spleen cells. One possibility is that stimulation and suppression are exerted by different subpopulations of immunocompetent cells present in the thymus, and that at high cell doses the suppressor cell activity is counteracted by helper cells. It may also be that heterogeneity exists in the adult spleen B cell population and that subpopulations

of immature B cells and therefore the effects may be of the same kind as those we report.

It is still not known whether the enhancing and suppressing activities of T cells on antigens like PVP are mediated by the same or by different subsets of T cells or thymus cells. In either case, the possibility of detecting helper cell activity or suppressor cell activity, evident from our data, depends on the stage of maturation of the B cells used in the experiments.

Table 4 Helper and suppressor effects of thymus cells: variations with cell dose

Normal thymus	Antibody titre*	
	Adult spleen	Young spleen
—	3.8 ± 0.2	1.0 ± 0.5
4×10^7	2.6 ± 0.7	0.9 ± 0.6
2×10^7	4.0 ± 0.0	1.0 ± 0.5
10^7	$0.0 \pm (< 1.0)$	3.4 ± 0.3
5×10^6	4.4 ± 0.2	3.7 ± 0.2
2×10^6	4.2 ± 0.5	3.8 ± 0.4
10^6	3.3 ± 0.8	ND

*Experimental conditions as in Table 2. For adult spleen, five recipient mice per group; for young spleen, eight to ten mice per group. ND, not determined.

of B cells with different requirements for helper T cells exist. The young spleen cells can be stimulated by relatively small doses of thymus cells and when the thymus cell dose is increased over a critical level (10^7 thymus cells for 2×10^7 young spleen cells) suppression is taking place. This could be due to heterogeneity of thymus cells, that is, different subsets of cells exerting suppression and stimulation. One population of T cells exerting both functions but effective at different optimal concentrations would give the same picture.

The humoral antibody response to PVP was found to be thymus-independent in adult thymectomised, lethally irradiated and bone marrow-reconstitution mice 3–4 weeks after the reconstitution, when presumably the B cells were as mature as those of normal adult mice⁴. We would, therefore, like to modify the concept of thymus independence for this antigen in the following way. Mature B cells respond to PVP without T-cell help. Under certain experimental conditions T cells may instead suppress the response, as evidenced from numerous publications of suppressor T cells during the past few years in a variety of systems¹³ including the anti-PVP system of mice^{14–16}. Immature B cells from young mice require T cells as helpers to respond optimally to PVP. There is at least one previous publication indicating that the concept of T cell dependency in immature B cells may be a more general phenomenon: it has been reported that the B cells from Peyer's patches in mice are poorly stimulated by the B-cell mitogen *E. coli* lipopolysaccharide¹⁷ and that the mitogenic response is enhanced by the addition of T cells. The Peyer's patches may contain a high propor-

Absence of age-resistance in neonatally thymectomised chickens as evidence for cell-mediated immune surveillance in Marek's disease

MAREK's disease virus (MDV) of chickens induces lymphomas and other lymphoproliferative changes, which, depending on the virulence of the strain used, may terminate in paralysis and death. Chickens genetically selected for resistance, however, are refractory to clinical MD and most chickens that are fully susceptible when young develop resistance as they become older. Resistance acquired with age is expressed through lesion regression^{1,2}. Our studies with genetic and age resistance established that humoral immunity did not play a major role in either type of resistance^{3,4} and now we present evidence that the thymus-dependent immune system is of principal importance in the natural resistance of old chickens.

Two experiments were conducted. White Leghorn chickens of cross 15×7 with maternal MDV antibody were either thymectomised (TX) or TX and treated with cyclophosphamide (CY, Cytosan, Mead Johnson Laboratories, Evansville, Indiana) at hatching. These and appropriate control groups were raised in isolation until 8 weeks old; and then inoculated intra-abdominally with cell-associated MDV (JM strain). Before virus inoculation, all groups were tested⁵ and found to be free from adventitious infection with MDV. Chickens were observed for 12 and 14 weeks after inoculation, in the first and second experiments respectively. Chickens dying during the observation period and those surviving at the termination of the experiments were necropsied and if gross lesions of MD were absent, peripheral nerves and gonads were examined for histological lesions⁶. The survivors were also tested for MDV antibody by the agar gel precipitin test. In TX groups, only the chickens that lacked grossly detectable thymus remnants were considered adequately TX and included in the data.

Table 1 T-cell and B-cell functions in chickens thymectomised (TX) and thymectomised plus cyclophosphamide (CY) treated at hatching (experiment 2)

Treatment at hatching	No. of chickens	Thymus remnants	Delayed hypersensitivity +/tested	Sheep erythrocytes (Haemagglutination test) +/tested†	Mean titre (log ₂)‡	Antibody to* <i>B. abortus</i> (Plate agglutination test)		MDV (agar gel precipitin test) +/tested
						+/tested	Mean titre (log ₂)	
γ-radiation	16	Present	15/16	15/15	6.9	15/15	2.5	16/16
TX + γ-radiation	9	Absent	4/9	9/9	7.4	9/9	3.4	2/2
TX + γ-radiation + CY	11	Absent	3/11	0/11	0.0	0/11	0.0	0/2
CY treated	15	Present	15/15	10/15§	3.7	1/15	3.0	0/14
None	13	Present	13/13	13/13	8.8	12/13	1.8	13/13

* All groups were inoculated intravenously with sheep erythrocytes and *B. abortus* (2.5×10^8 cells of each) at 5 and 7 weeks of age and with MDV (intra-abdominally) at 8 weeks. Antibody to sheep erythrocytes and *B. abortus* was determined just before MDV inoculation. Tests for MDV antibody were done at the end of the experiment.

† Titre of $\geq 1:4$ was considered positive.

‡ Highest dilution tested was 1:512.

§ Five chickens negative by the haemagglutination test were also negative for antibody against *B. abortus*.

Chickens were thymectomised surgically⁵ within 30 h of hatching. On the day following surgery, TX and appropriate control chickens were exposed to 600 rad of total body γ radiation (88 rad min⁻¹ at 2 m from cobalt-60, 24,000 Ci, Michigan State University). Thymus function was tested by delayed-type hypersensitivity (DTH) reaction. Chickens were sensitised with complete Freund's adjuvant and 4 weeks later, tested for local reaction to intradermal injection of old tuberculin into the right wattle⁶.

Deficiency in the B-cell function was induced with 16 mg of CY given in four daily injections, each of 4 mg, commencing 2 d after hatching. In the CY-treated groups, only chickens that failed to produce antibody against sheep erythrocytes, *Brucella abortus* and MDV were included in the data (Table 1).

In the first experiment all survivors in MDV-inoculated but none in uninoculated control groups had MD antibody at termination. As Fig. 1 shows, the group exposed at 8 weeks had a significantly lower incidence of gross lesions and mortality than the group exposed at 1 d ($P < 0.01$, χ^2 test), thus demonstrating age resistance in the older chickens. As observed earlier^{1,2}, however, age resistance was not well pronounced at the level of microscopic lesions. The incidence of gross lesions and mortality in the γ-irradiated older group was slightly higher, although not significantly ($P > 0.5$), than that in untreated 8-week-old chickens. Like the unirradiated chickens, the irradiated chickens had a significantly lower incidence of gross lesions and mortality than that in the 1-d-old group

($P < 0.01$) thus illustrating the presence of age resistance. In the TX group, 24 chickens lacked thymus remnants at necropsy: 13 of these were negative for DTH. Among the 24 TX chickens, the incidence of mortality and gross lesions was 87%; significantly higher than that in the untreated ($P < 0.01$) and γ-irradiated 8-week-old groups ($P < 0.01$). In the second experiment (Fig. 2) the resistance of 8-week-old chickens was more pronounced than in the first. Incidence of death and gross lesions was 15%, whereas incidence in the 1-d-old group was 90%. γ Irradiation did not significantly influence the resistance of older birds. The thymus- and bursa-dependent functions of various treatment groups in the second experiment are given in Table 1. Of the 15 CY treated chickens, five were free of antibody against sheep erythrocytes and *B. abortus*. Four of the five were resistant, however, confirming that humoral immunity alone does not play an important role in age resistance to MDV. All 9 chickens in the TX and 11 in the TX + CY treated groups either died as a result of MD or had gross lesions at termination. These results were consistent with the results of the first experiment. Because CY treatment alone did not influence resistance, the lack of resistance in the TX + CY treated group was attributed to thymectomy. The incidence of microscopic lesions in older age groups was lower than in the first experiment probably because chickens were held longer and more lesions regressed.

The effect of the absence of T cells on MDV has not previously been reported, presumably because T-cell function cannot be completely obliterated with available surgical procedures. In our experiments also, thymectomy failed to eliminate all T-cell function because many TX birds, although lacking in detectable thymus remnants, reacted in DTH to old tuberculin. T-cell function was, however, definitely suppressed to significantly alter the MD response.

The results of this study also have important implications for the understanding of the pathogenesis of MD. The mechanism by which lymphoid cells are triggered to proliferate into lymphomas is not known. Because most of the lymphoma cells in MD are of T origin^{7,8} and because functional bursectomy does not influence lymphoma formation^{9,10}, it has been proposed that the target cell, that is the cell that undergoes neoplastic transformation, is of thymic origin. Several lymphoid cell lines have been developed from MD lymphomas¹¹⁻¹³ and the cells of these lines bear T-cell surface markers^{13,14}. In the light of this evidence for the T cell being the target cell for MD virus the high incidence of gross lesions in the TX birds in our experiments was unexpected. Our results can, however, be explained if, as stated above, neonatal thymectomy did not eliminate all T cells and the TX birds had enough remnant T cells to serve as the target for MDV, yet insufficient to mount a satisfactory cell-mediated immune response. The residual T cells may have originated from thymic remnants¹⁵ or from cells that had left the thymus before thymectomy. Nonetheless, our results indicate a pressing need for a more direct identification of the target cell in MD. Recognition of specific tumour

Fig. 1 The effect of neonatal thymectomy (TX) and γ-radiation (γ) on age resistance to MDV. Numbers below columns indicate the age in days (d) or weeks (w) at the time of MDV inoculation (1.0×10^4 PFU per chicken). Numbers above columns indicate the number of chickens in each group. Total MD includes chickens with histological lesions at termination of the experiment. Black indicates mortality plus gross lesions and white indicates total MD.

Fig. 2 The effect of neonatal thymectomy (TX) and γ -radiation (γ) and of TX- γ and cyclophosphamide (CY) treatment on age resistance to MDV inoculation (5.5×10^4 PFU per chicken). See legend to Fig. 1.

antigens¹³ may facilitate detection of transformation *in vivo*.

If T cells acted as target cells, the presence of the thymus was apparently not necessary for initial virus-cell interaction and for emergence of transformed clones. Because gross lesions were found in most chickens without thymus remnants, the initial transformation probably occurred in extra thymic T cells. This situation is in contrast with that of lymphoid leukosis in chickens where virus-induced transformation of target cells originates in B cells within the physical confines of the bursa of Fabricius and the removal of this organ, even well after many B cells have peripheralised, prevents tumour formation^{16,17}.

We concluded that age resistance and hence lesion regression in MD is mediated through thymus-dependent cellular immune functions.

We thank Dr B. R. Burmester for advice and encouragement, Dr W. Kwolek for statistical analyses, and Mrs Evelyn Young, Miss Karen Sorensen and Mr Barry Coulson for technical assistance.

Effect of ascorbic acid on hyaluronidase inhibitor

THE presence of a physiological inhibitor of hyaluronidase (PHI) in mammalian serum was suggested by Duran-Reynals¹ who observed the destruction of spreading factor by blood. Hobby *et al.*² and McClean³ later reported the inhibition of microbial and mammalian hyaluronidase by serum. PHI, which is a glycoprotein and sensitive to heat⁴,

has been shown to increase in both bacterial and viral infections, cancer and various liver, kidney and rheumatic diseases^{4,5}. A small increase of PHI has been reported in scorbutic guinea pigs by Shack *et al.*⁶. These increases have been suggested^{5,8} to represent a defence against invasive microorganisms, or a non-specific response to tissue inflammation or destruction⁷. (Fischer-Szafarz⁷ described a hyaluronidase inhibitor in the serum of cancer patients which she believes is different from PHI.) Cameron and Pauling suggested that a high intake of ascorbic acid increases the biosynthesis of PHI, resulting in a decrease in hyaluronidase activity⁹. Consequently, the invasiveness of proliferative diseases would be prevented by reduced depolymerisation of the intercellular matrix of the proliferating cells. We have investigated the effect of doses of ascorbic acid of 0–1,000 mg kg⁻¹ d⁻¹ on levels of PHI in the serum of guinea pigs. Our results show that PHI is not affected by high levels of dietary ascorbic acid.

Guinea pigs receiving 20, 200, 400 and 1,000 mg kg⁻¹ d⁻¹ gained weight at identical rates throughout the experiment. Those animals which received no ascorbic acid lost weight after 14 d and developed scurvy (Fig. 1).

Fig. 1 Effect of ascorbic acid on body weight. Adult male Hartley guinea pigs were fed a vitamin C-deficient Reid Briggs diet and received varying amounts of ascorbic acid in drinking water for 22–23 d. Based on an average daily water consumption of 10 ml per 100 g body weight, the animals received 0, 20, 200, 400 or 1,000 mg kg⁻¹ d⁻¹. Body weights were measured periodically. +, Untreated; o, 20 mg kg⁻¹ d⁻¹; x, 200 mg kg⁻¹ d⁻¹; Δ, 400 mg kg⁻¹ d⁻¹; □, 1,000 mg kg⁻¹ d⁻¹. Each point represents the mean of 15 animals.

In experiment 1 the serum from each animal was assayed individually for PHI by the hyaluronidase turbidity assay (Table 1). Scorbutic guinea pigs had significantly more PHI ($P < 0.02$) than those receiving 20 mg kg⁻¹ d⁻¹ and there was no significant difference in levels of PHI among any of the groups receiving ascorbic acid. In experiment 2 (Table 1) sera from 15 animals were pooled in groups and assayed for PHI. Again the levels of PHI in the scorbutic group were significantly ($P < 0.01$) higher than in animals receiving ascorbic acid. Again there was no significant difference in PHI levels in the groups receiving ascorbic acid. Sera from animals in experiment 1 were then pooled and assayed for PHI using ³⁵S-chondroitin sulphate (ChS) as a substrate for hyaluronidase (Fig. 2). The greatest inhibition of hyaluronidase activity was achieved with sera of scorbutic animals. Animals receiving 200 or 400 mg kg⁻¹ d⁻¹ of ascorbic acid did not have a greater level of PHI than those receiving 20 mg kg⁻¹ d⁻¹.

Since scorbutic guinea pigs consume less food than normal animals, we investigated the effect of this decreased food

Fig. 2 Hydrolysis of ^{35}S -chondroitin sulphate by hyaluronidase. ●, Hyaluronidase control; +, hyaluronidase preincubated with sera from untreated animals; ○, hyaluronidase preincubated with sera from animals treated with 20 mg ascorbic acid $\text{kg}^{-1} \text{d}^{-1}$; x, hyaluronidase preincubated with sera from animals treated with 200 mg ascorbic acid $\text{kg}^{-1} \text{d}^{-1}$; ▲, hyaluronidase preincubated with sera from animals treated with 400 mg ascorbic acid $\text{kg}^{-1} \text{d}^{-1}$; ○, boiled hyaluronidase. The conditions for preincubation of the PHI and hyaluronidase were identical with those described for Table 1, except that 6.0 ml of enzyme was preincubated with 0.2 ml of guinea pig serum. After preincubation 3.0 ml of the hyaluronidase-PHI mixture was added to 3.0 ml of 0.3 M phosphate buffer, pH 5.5, containing 13 μg of ^{35}S -chondroitin sulphate (800,000 c.p.m.). The reaction was maintained at 37°C for 1 h. Samples (1 ml) were removed at the designated times and added to 1 ml of 2% cetylpyridinium chloride. After 2 h at room temperature, the precipitate was centrifuged, and 0.5 ml of supernatant was placed in 10 ml of Aquasol, and counted in a Packard liquid scintillation counter. The ^{35}S -chondroitin sulphate was isolated from costal cartilage which had been incubated in Krebs-Ringer bicarbonate containing 0.2 mCi of carrier free $\text{H}_2^{35}\text{SO}_4$.

In experiment 1 PHI units were measured in the serum of each of the 15 animals in each group. In experiment 2 they were measured in sera pooled from the 15 animals in each group, and each serum pool was assayed nine times.

^{*}Each value represents the mean \pm standard deviation.

[†]Hepatic ascorbic acid was determined in each animal by the method of Roe *et al.*¹⁰

[‡]Blood was withdrawn on the last day of each study by cardiac puncture, and serum PHI was determined according to the method of Dorfman *et al.*¹¹ with the following modifications. Guinea pig serum (25 μl) was added to 1.0 ml of solution containing 2.5 μg of bovine testicular hyaluronidase (Worthington), 0.02 M phosphate buffer, pH 7.0, 0.001 M MgCl_2 , 0.45% NaCl and 0.01% bovine serum albumin. The hyaluronidase-PHI mixture was incubated for 10 min at room temperature. After 10 min, 0.5 ml of the mixture was added to 0.5 ml of 0.3 M phosphate buffer, pH 5.5, containing 0.2 mg of hyaluronic acid. The reaction was maintained at 37°C for 40 min, and then terminated by the addition of 5.0 ml of acid albumin. The resulting turbidity was allowed to develop for 10 min before reading at 600 nm on a Zeiss spectrophotometer.

intake as a factor in increased PHI in scorbutic animals. PHI and hepatic ascorbic acid were assayed in animals receiving 20 $\text{mg kg}^{-1} \text{d}^{-1}$ of ascorbic acid by oral intubation and then fasted for 0, 24, 48, or 72 h. There was little or no change in PHI or ascorbic acid as a result of fasting.

There can be a tenfold increase in serum PHI in certain diseases⁵. Table 1 and Fig. 2 show a modest but significant increase in the PHI levels of scorbutic animals compared with those receiving 20 mg ascorbic acid $\text{kg}^{-1} \text{d}^{-1}$.

These observations confirm the results of Shack *et al.*⁶ who showed an increase of approximately 40% in the PHI of scorbutic guinea pigs compared with animals on a normal diet. Our results do not support the hypothesis of Cameron and Pauling⁷ that ascorbic acid may ameliorate proliferative diseases by increasing biosynthesis of PHI. We did not find any significant change in the PHI of animals receiving 20–1,000 mg ascorbic acid $\text{kg}^{-1} \text{d}^{-1}$.

matters arising

High affinity uptake of neurotransmitter amino acids

LEVI and Raiteri¹ have concluded that their results on the uptake and release of ³H-GABA by rat brain synaptosomes indicate that homoeexchange is a major mechanism by which radioactive GABA enters synaptosomes when low substrate concentrations are used. They therefore question the effectiveness of high affinity uptake mechanisms in terminating the postsynaptic actions of this and other neurotransmitter amino acids after their release from presynaptic nerve terminals in the central nervous system (CNS)^{2,3}.

I believe that their conclusion is misleading. It is based largely on two findings. First, that unlabelled GABA or glycine in low concentrations stimulate the efflux of ³H-GABA or ³H-glycine from synaptosomes previously labelled with these amino acids. These experiments were conducted, however, with synaptosomes that had been incubated for 10 min in 0.5 μ M labelled amino acid; from our own experience with such preparations we have found that the accumulation of tritiated amino acid is by this time approaching a steady state, in which the rate of influx is approximately equal to the rate of efflux, that is, a homoeexchange situation may exist. Addition of exogenous unlabelled amino acid in these conditions would therefore be expected to lead to the increased efflux of labelled amino acid observed by Levi and Raiteri¹.

These results do not contradict the hypothesis that the initial rate of influx of labelled GABA or glycine into synaptosomes or brain slices incubated *in vitro* represents a net accumulation of amino acid in the intracellular space. Previous observations⁴ by Levi and Raiteri and our own results⁵ have shown the initial rate of influx of labelled GABA into synaptosomes or brain slices is unaffected either by large increases in the size of the intracellular GABA pool induced by previous incubation in a medium containing a high concentration of the amino acid, or by treatment of animals with the GABA-glutamate transaminase inhibitor amino-oxyacetic acid. These findings are hard to reconcile with the notion that the accumulation of labelled

GABA occurs largely by homoeexchange, as if this were so the initial rate of influx of labelled GABA should be increased in such conditions.

Second, Levi and Raiteri measured the net removal of GABA from the incubation medium when synaptosomes were incubated with ³H-GABA at concentrations from 1 to 10 μ M. They show that the net uptake of amino acid is less than that expected from measurements of the removal of radioactivity from the medium, although approximately 40% of the total radioactivity removed could be accounted for by a net accumulation of GABA. These results, however, are in complete disagreement with those of similar experiments from the same laboratory⁴ which showed that net uptake of GABA accounted for more than 95% of the uptake of ³H-GABA in synaptosome preparations from various regions of rat CNS incubated with 20 μ M ³H-GABA. Aprison and McBride also observed a net accumulation of glycine in rat spinal cord synaptosomes when these are incubated with low concentrations of glycine (37.5–150 μ M).

The results of Levi and Raiteri also disagree with our previous findings² which showed that a net uptake of GABA accounted for more than 80% of the total uptake of ³H-GABA in rat brain slices incubated with 200 μ M GABA. In these conditions the uptake of exogenous GABA led to more than a threefold increase in the total GABA content of the tissue.

Nevertheless, after a 30 min incubation with this relatively high concentration of exogenous GABA there was also a significant exchange between the endogenous GABA content of the tissue and ³H-GABA in the external medium². Such exchange is not unexpected and does not contradict the conclusion that high affinity transport mechanisms for amino acids are capable of a net removal of amino acid from the external medium, and can thus represent important mechanisms for terminating the actions of these pharmacologically active substances in the CNS.

LEVI AND RAITERI REPLY—When synaptosomes are incubated in a definite volume of medium containing a very low ³H-GABA concentration, the steady-state accumulation that is approached after a few minutes does not correspond to a saturation of the synaptosomal uptake capacity, but is a relative value which depends on the concentration of GABA in the medium and on the ratio between the amount of tissue and the volume of medium. If the same amount of synaptosomes is either incubated in a larger volume of medium or, even more so, if it is superfused with this medium, uptake continues to increase for a much longer period. Moreover, similar uptakes of 10 and 20 μ M ³H-GABA were obtained in synaptosomes that had been preincubated in the presence or in the absence of 0.5 μ M unlabelled GABA, and similar results were obtained in superfusion exchange experiments when synaptosomes were preincubated in 0.05 μ M ³H-GABA instead of 0.5 μ M. For these reasons the synaptosomes used in our experiments¹ must be considered as prelabelled, and not as preloaded to an "absolute" steady state.

If one accepts this concept, and assumes, as is generally done, that the labelled GABA mixes with the endogenous pool, then our results do show that homoeexchange is an important mechanism by which labelled GABA is accumulated by synaptosomes, particularly when low GABA concentrations are used. As homoeexchange has never been considered to contribute significantly to the initial rate of uptake of radioactive GABA by nerve terminals, in our opinion it is not possible, at present, to say whether the net uptake of this amino acid (which we did not deny) has or has not a high affinity component (K_m between 4×10^{-7} M (ref. 2) and 2×10^{-5} M (ref. 3)). We suggest that, even if, a high affinity component did not exist, a low affinity uptake system (K_m of the order

of 10^{-3} M) might still be effective for the synaptic inactivation of GABA. The data of Fonnum *et al.*⁴, who estimated the concentration of GABA in 'gabergic' nerve terminals to be "at least 60 mM, probably over 100 mM", seem to support this suggestion.

As to the other comments raised, we are obviously aware of the fact that our present data disagree with previous experiments conducted in our own as well as in other laboratories. This did not seem to us a strong enough reason not to publish the data. Moreover, the disagreement is often more apparent than real, and in most cases concerns the interpretation of the data rather than the data themselves. For example, the finding² that cortex slices (which contain structures other than nerve endings) show a net uptake of GABA after 30 min of incubation in the presence of a concentration (200 μ M) at which high affinity uptake^{3,5,6} and exchange¹ are virtually saturated, does not disprove that homoeexchange can account for a large part of the initial rate of accumulation of radioactivity by synaptosomes incubated with 1 or 10 μ M ³H-GABA.

Similarly, our data on glycine (detectability of homoeexchange in spinal but not in cortical synaptosomes) are not disproven by those of Aprison and McBride⁷ who did show a net uptake of unlabelled glycine, but did not assess the contribution of exchange to the accumulation of radioactive glycine. Moreover, these authors may have somewhat overestimated net uptake, as they did not consider the increase in glycine concentration that might have occurred in the tissue on incubation without added glycine⁸.

The similarity between radiochemical and chemical uptake of 20 μ M GABA that we found in a previous study⁹ is difficult to explain at present. In this type of experiment the choice of a correct type of control is very critical, and we are now trying to determine whether an overestimation of net uptake might have resulted from the type of control chosen.

The results of the experiments in which the tissue concentration of GABA was artificially increased^{9,10} could have several explanations: for example, the increased intracellular concentration of GABA may cause a concomitant inhibition of net uptake and a stimulation of homoeexchange. In appropriate experimental conditions we have shown that the accumulation of radioactive GABA is increased in synaptosomes prepared from amino-oxyacetic acid-treated rats.

We take this opportunity to mention that one of the data reported in Fig. 2 of our letter¹ was wrong, because of a trivial technical error. The figure showed a rapid and massive depletion of synaptosomal GABA content and

the absence of any detectable homoeexchange on superfusion with a sodium-free medium. Our latest data (Raiteri *et al.*, unpublished) indicate that superfusion with sodium-free medium (NaCl replaced by sucrose) does not cause a significant increase in the spontaneous release of ³H-GABA from purified synaptosomes. They do confirm, however, that, in the absence of sodium—homoeexchange is 95–100% inhibited. Therefore, the error does not invalidate the conclusion that absence of homoeexchange could account for what looks like inhibition of the high affinity uptake of GABA.

Playing possum

IN his interesting article on the opossum α haemoglobin chain sequence, Stenzel¹ states that 'a selectionist interpretation of the more rapid rate of molecular evolution in a living fossil is possible' because we may expect more rapid molecular evolution 'accompanying slow morphological changes because the reduced number of loci undergoing substitutions may sustain more intense selection per locus'.

Perhaps this is so, but selectionists can cite scripture for their own purpose. Neutralists, however, are delighted to find that this molecule of a living fossil underwent changes at least as rapidly as the

homologous molecules in highly-evolved species. This supports the thesis that 'there seems to be considerable latitude at the molecular level for random genetic changes that have no effect on the fitness of the organism' (ref. 2).

Sunspot cycle periodicities

THE Maximum Entropy Spectral Analysis technique of Burg (unpublished) and Cohen and Lintz¹ has led to the discovery of periodicities in sunspot data and an ability to predict ionospheric reflectivity and climatic features. But the theory that a planetary influence affects sunspot variations^{2–4} still cannot be ruled out, as is shown by a further analysis of the data of ref. 1.

I accept the 11.05 ± 1.5 , 9.8 ± 0.1 , and 8.15 ± 0.15 yr terms found by Cohen and Lintz but wish to choose another way of describing the cause of their 89.6 yr peak. The proposed fundamental beat tone of 179 yr just does not appear in their periodogram nor is it the beat period suggested. At about one half that value (also the true value of the beat period they have proposed) there is a fairly broad resonance. But 89.6 yr (really more like 86 skewed) is the value one obtains when oppositions and conjunctions of Uranus and Neptune are considered as a possible cause. The relative phase of these two planets is at quadrature during the peak sunspot maxima of 1778, 1864 and 1950 and in conjunction or opposition at the least sunspot maxima of 1821, 1907 and 1993 (predicted). I found the same periodicity but different significant phase relationships when I compared the relative positions of Uranus and Neptune to peak periods of energy released by terrestrial earthquakes². Because of the special phase relationships between the sunspot and planetary data, I feel the 86 yr 'tone' is really due to Uranus and Neptune.

Interestingly, the other periodic terms which Cohen and Lintz found can be explained as the resonance of the following planetary mean motions: (1) $J + S + U - N = 1/8.06$ yr; (2) $J + U + N = 1/9.78$ yr; (3) $J + U - N = 1/11.09$ yr.

Matters arising

Matters Arising is meant as a vehicle for comment and discussion about papers that appear in *Nature*. The originator of a Matters Arising contribution should initially send his manuscript to the author of the original paper and both parties should, wherever possible, agree on what is to be submitted. Neither contribution nor reply (if one is necessary) should be longer than 300 words and the briefest of replies, to the effect that a point is taken, should be considered.

reviews

Missing some of Darwin's brilliance

Darwin on Man: A Psychological Study of Scientific Creativity. By Howard E. Gruber. (Together with Darwin's early and unpublished notebooks, transcribed and annotated by Paul H. Barrett.) Pp. xxv+495. (Wildwood House: London, September 1974.) £5.00.

HOWARD E. GRUBER and Paul H. Barrett have produced a book which they hope will elucidate the roots of Charles Darwin's achievement. They believe that the six notebooks which Darwin kept in the years 1837-39 contain crucial evidence for an analysis of his scientific creativity. Sir Gavin de Beer and his collaborators have already published the four notebooks on the transmutation of species. The Gruber-Barrett volume now presents for the first time a complete transcription of Darwin's two notebooks (designated M and N) on man, mind, and materialism, along with several of his other unpublished contemporary documents on the same subjects. They also reprint some crucial passages from previously published documents, primarily the notebooks on transmutation of species. Barrett transcribed the manuscript materials and has provided detailed bibliographic notes, which are supplemented by Gruber's useful commentaries summarising both the M and N notebooks.

Gruber's primary contribution to the volume is a 257 page analysis of Darwin's scientific creativity, in which the M and N notebooks play a prominent role. Gruber presents two major theses. He first argues that Darwin's invention of the theory of evolution by natural selection between 1837 and 1839 was not the result of a "golden moment of insight", but was instead the culmination of a gradual process involving many levels of thought. This illustrates the belief of Gruber (and Jean Piaget, who wrote a laudatory foreword to the book) that creativity is generally a more gradual process than most people realise. His second thesis is that the M and N notebooks hold "the key to understanding the essential role of his ideas about man and mind in his thinking about evolution". Gruber concludes

Charles Darwin: spent his life refining the original theory

that Darwin's materialism is evident in these notebooks, and that he delayed publication of his conception of evolution by natural selection because he feared persecution and ridicule for his materialism.

Gruber's thesis that Darwin's creation of the theory of evolution by natural selection was a gradual and cumulative process is convincing. But scientific creativity is elusive, and the details of Gruber's analysis are fraught with difficulties. His chapters on the Darwin family *Weltanschauung* and Darwin's teachers contain precious little evidence about actual influences upon Darwin himself. The crucial evidence about his scientific creativity comes from the notebooks. Yet what are these notebooks? They contain Darwin's hurriedly written impressionistic speculations, including his gleanings from other literature mixed indistinguishably with his own ideas. Many of the passages, especially in the M and N notebooks, are unclear or contradictory. We have no way of knowing which passages Darwin considered important or trivial at the time that he wrote them. We can, however, agree with Darwin's later assessment that much in the notebooks is trivial or worthless, even for the historian. To

recreate Darwin's creativity from these notebooks is terribly difficult.

To simplify matters, Gruber explicitly ignores Darwin's ideas about heredity, a serious omission which he acknowledges. He then proceeds, like a classical scholar working on Anaximander's one fragment, to make much of little. He finds in Darwin's notebooks an "underlying order" which completely escapes me. In constructing logical systems out of Darwin's speculations, he is led into contradictions. For example, Gruber argues that Darwin's brief mention of "monads" is really a whole theory of evolution, and that the "monad theory contains the principle of spontaneous generation". Later, Gruber argues that Darwin gave up the theory of spontaneous generation, influenced by Ehrenberg's claim that extant lower organisms were identical with fossil forms. The problem with this scenario is that Ehrenberg is mentioned in the very first passage of Darwin's supposed 'monad theory'. So although Gruber's thesis about the gradual nature of Darwin's creativity is reasonable, the details of his creative process remain obscure.

Gruber's second thesis, that the M and N notebooks and associated docu-

ments contain much about Darwin's views on man, mind, and materialism in relation to evolution, is certainly true. Indeed, the major significance of this book lies in showing that at a very early stage Darwin understood that his idea of evolution by natural selection had vast materialist implications for human evolution and psychology.

Yet Gruber's conclusion that Darwin put off publication of his ideas primarily from fear of persecution and ridicule for his materialist ideas is drawn from shaky evidence. Gruber even resorts to interpreting a dream briefly reported by Darwin, and argues that a photograph of Darwin taken in 1854 reveals "the strain of long years of delay".

A different interpretation is possible. Darwin had high standards for his published work. He later commented that he benefitted from the delay in publishing his works on evolution because he was able to gather better evidence and think through possible objections. Perhaps he was motivated not so much by fear of ridicule as a materialist, as by the feeling that his own standards of argument and evidence had not been attained.

After giving the impression that he admires Darwin's materialism, Gruber's last chapter, "Creative Thought: The Work of Purposeful Beings", contains a surprise. His theory of creativity is vitalistic nonsense. It follows the tradition of Alfred Russel Wallace's mysticism (after 1864) rather than Darwin's materialism. Gruber's theory is that each individual organism functions "according to its own internal laws or organisation". When two organisms interact, the result is

behaviour which is utterly unpredictable from a consideration of the special laws governing the individual organisms. A human has, in addition, an internal unpredictable creativity resulting from the interaction of the separate parts of his thought, each of which has a life of its own. So in the end the reader discovers that in his analysis of Darwin's creativity, Gruber is conducting the inquiry under the assumption that the creative process is inherently inscrutable. Darwin spent his life reducing complex biological behaviour to materialist laws. He intensely disliked Wallace's mysticism about human minds, and he would have been appalled to have Gruber's vitalistic theory applied to himself.

Does this book as a whole open up a fruitful field of Darwin research? I hope not. By focusing almost entirely upon Darwin's theory construction of 1837-39, the authors have missed the most important and influential part of Darwin's genius. As he himself believed, Darwin is important not because he outlined the theory of evolution by natural selection in the late 1830s, but because for the rest of his life he refined and supplemented the theory, found evidence for it, and presented it in enormously influential published works. Michael Ghiselin's *The Triumph of the Darwinian Method* (The University of California Press: Berkeley and London, 1973) is a step in the right direction, but the vast and important problem of Darwin's influence through his letters and published works in the second half of the nineteenth century has scarcely been touched. The M and N notebooks seem inconsequential in comparison. **William B. Provine**

Elementary world climatology

World Climatology. By John G. Lockwood. Pp. xiv+330. (Arnold: London, March 1974.) £8.50.

THE study of climatic change and its effect on the environment is one of the most important branches of modern science, in terms of the potential direct effects on the lives of non-scientists. As a result of developments in several fields including studies of the Earth's magnetic field and astronomy, as well as the more conventional aspects of meteorology (which now include use of satellite observations and high speed computers), a synthesis leading to an understanding of at least some aspects of climatic change seems to be in the offing. As a result, many people who have no formal training in meteorology are working in areas where some detailed understanding of the working of the atmosphere is essential. Those people would find this book invaluable.

World Climatology is not concerned with climatic change at all, but with the physical basis of climatology with particular reference to environmentally important aspects. It is intended, says the author "for students taking university courses on climatology, particularly those at an advanced level" and the reader is warned that an acquaintance with basic concepts of meteorology, mathematics and physics is required. But these assumed basics are, in fact, at the most elementary level, and the book introduces gently such concepts as the Stefan-Boltzmann law of black body radiation.

The first part of the book deals with the basics of climatology: radiation laws, convection and turbulence, precipitation and evaporation, and local microclimates (ranging down to that at the surface of a plant leaf). The second and third parts apply these basics to the low latitude atmosphere and to the atmosphere of middle and high latitude regions. With a generous sprinkling of figures—one or more clear and informative line drawings on most pages—and well written text this makes the book ideally suited for its intended readership, but equally valuable to anyone trying to fill in a knowledge of climatology which is sketchier than it should be.

The publishers of this book have done an excellent job. The clarity of the figures is matched by the clarity of the text. There is a generous bibliography, in the form of references at the end of each chapter.

This book is a good place to find out about the basics of climatology.

John Gribbin

The second messenger about to be galvanised into action by a message from the outside. From *Membranes and their Cellular Functions*. By J. B. Finean, R. Coleman and R. H. Michell. Pp. vi+123. (Blackwell Scientific: Oxford, 1974.) £2.80.

The Physics of Time Asymmetry. By P. C. W. Davies. Pp. xviii+214. (Surrey University Press; Leighton Buzzard, 1974.) £6.50.

THIS book is about what is popularly called the 'arrow of time' but the author does not much like the term because the asymmetry is that of the world in respect to time, not of time itself. The book is a critical study of the origin of the asymmetry and of its role in basic physics. Indeed, it could serve as the making of an excellent course on the foundations of physics.

With the only known exception of properties of K mesons, the laws of physics are symmetric in regard to time, and so the asymmetry must arise from boundary conditions. Davies proceeds from that consideration to two important inferences. First, that irreversibility in the Universe depends ultimately on gravitation, since any sizeable body in the Universe is held together by its own gravitation and there is no permanent equilibrium state for such a body. Second, that all important aspects of time asymmetry are traceable to the beginning or end of the Universe. Both bring the subject naturally into the realm of cosmology. Appropriately, the chapter in the centre of the book is on "Thermodynamics and cosmology". Moreover, the fact that in ordinary electromagnetism we consider only retarded effects is nowadays generally explained by the 'absorber' theory of radiation, and so it again relates the subject to cosmology. Whether or not the thermodynamic and electromagnetic properties are independent seems to remain an open question. Davies discusses all that in his next chapter. Thermodynamic irreversibility is bound up with probability theory, and a more fundamental sort of probability is involved in quantum mechanics, as is then described. Finally, Davies discusses the bearing of the whole subject upon the choice of a cosmological model.

Davies skilfully conveys the flavour of the mathematical treatment without going into its details. His presentation tends to be over-modest, and this inhibits him somewhat from stating categorically the conclusions reached at each stage of the development of the topic—the reader has to do a little searching to find them. Nevertheless, "Having completed this book", he makes bold to conclude that (Introduction, page 7), "the basic framework for understanding the nature of time asymmetry is clearly available, and it is unlikely that any future considerations of detail will introduce anything qualitatively new". Although the book certainly seems to do more than any

other towards achieving this happy outcome, one is left with an uneasy feeling that something is still missing. The old problem of the relationship between the indeterministic world of quantum physics and the fully deterministic world of general relativity seems still imperfectly understood. Actually, Davies exposes the difficulties in his section 6.3, "Quantum measurement theory". I cannot but conjecture that the place of the observer will somehow have to be recognised more extensively in formulating physical theory and that this will entail the admission of uncertainties associated with other physical constants besides Planck's constant.

The book most adroitly brings together all the main relevant lines of thought; whatever remains to be done must surely start from the ground so well surveyed by Dr Davies.

W. H. McCrea

Time and space

Space, Time and Spacetime. By Lawrence Sklar. Pp. xii+423. (University of California Press: Berkeley, Los Angeles and London, 1974.) \$15.00; £7.50.

LAWRENCE Sklar is a philosopher writing about philosophical aspects of space and time, from Newton and Leibniz to Einstein and Reichenbach. Nevertheless, his clear grasp of modern mathematics and physics, and his lucid exposition, make this book eminently suitable for physicists and mathematicians who wish to explore the philosophical background to their subject. Although the text is not in any sense mathematical, crucial topological and geometrical concepts are carefully explained before they are incorporated into the author's thesis.

The book is divided into four main sections. The first deals with the epistemology of geometry with a historical development leading up to Minkowskian and Riemannian spacetimes. Much attention is then devoted to Poincaré's proposition that the geometrical structure of the world is merely a matter of convention and to the existence of different hypotheses each equally capable of explaining the same observations. The complex web of argument and counter argument subdivides into many alternative points of view and may well frustrate the scientific reader who probably regards the whole issue as sterile overemphasis, especially as the author terminates the controversy with an admission of inconclusiveness.

Part two is concerned with absolute motion and the theory of relativity, tracing the controversy between the substantial view of Newton that space is an entity and the relational views of Leibniz and Mach that it's not there at all. The special and general theories of relativity are somewhat grafted on to this discussion without, of course, solving the problem. Sklar gives a fine descriptive account of the theories of relativity, which could well be used by physics students wishing simply to learn the subject. Even modern approaches such as geometrodynamics get a mention. At the end of this section the author presents his own rather unconvincing answer to the problem of the origin of inertial forces. Rejecting Mach for apparently aesthetic reasons and wishing to retain a pure relationist stance, he proposes that the statement "is absolutely accelerated" is not a relational term, giving it instead the status of a complete assertion. This may well be a valid philosophical contortion, but it is unlikely that the physicist will be satisfied with the denial of any explanation for inertial forces.

Part three of the book deals mainly with time—the usual problems of simultaneity, time dilation, twins paradox and so on in relativity theory—and also presents some bold treatment of bizarre topologies, including a discussion of trouser spaces, non-orientable manifolds and closed time-like world lines. The discussion is framed in the causal theory of time to which the last part of this section turns, concluding with the widely held belief that the theory is implausible.

The final section summarises briefly the fascinating and controversial subject of time asymmetry. The account suffers somewhat from superficiality, and the vital topic of Reichenbach's branch systems is not discussed in detail. The conclusion given to this section is that we simply 'know' the relation of temporal priority between events. This is a most unsatisfactory escape route, which does nothing to dispel the lamentable confusion which exists between the phenomenon of the psychological flow of time and time asymmetry as encountered in the objective world, and which is so prevalent among scientists and philosophers who write about time asymmetry.

This book is a comprehensive, well written and authoritative account of space and time which well suits both scientists and philosophers of science. It is inclined to be a little tedious and repetitive, but contains plenty of exciting and interesting material for students of these disciplines. P. C. W. Davies

obituary

Herbert Alexander Sober, a major innovator and developer of our current technology for the separation and purification of biologically important macromolecules, died of a heart attack in Washington, D.C., on November 26, 1974, following a relatively minor operation.

Sober was an undergraduate at the City College of the City of New York and received his Ph.D. degree in 1942, majoring in biochemistry at the University of Wisconsin. Following his graduate studies, he spent three years as a toxicologist and as Chief of the Analytical Research Group at Edgewood Arsenal near Baltimore. After two years at Mount Sinai Hospital in New York he joined the National Cancer Institute, NIH, as a member of the Commissioned Corps of the US Public Health Service, serving as Chief of the Laboratory of Biochemistry. In 1968 he transferred to the US Civil Service and took the position of Chief in the Laboratory of

Nutrition and Endocrinology, National Institutes of Arthritis, Metabolism, and Digestive Diseases. Sober is best known as co-developer, with Elbert Peterson, of the modified cellulose ion exchangers. These substances, which could be prepared in a wide variety of forms having either cationic or anionic characteristics, and possessing a wide range of intrinsic pK values, are extremely gentle to sensitive protein and nucleic acid systems and also exhibit excellent discrimination when combined with the principle of gradient elution for the separation of macromolecular mixtures. There are very few papers published in the biochemical or molecular biological literature that do not quote the use of the cellulose derivations as key tools in the experiments described. The value of these chromatographic techniques was recognised, in 1970, by the selection of Sober and Peterson for the Hillebrand Award, presented by the American Chemical Society of Washington.

The association of Sober's name with chromatography and its applications has tended to obscure his contributions to a number of other areas. He published nearly 150 papers during his career, including the ever-useful *Handbook of Biochemistry*. He was, for example, involved in the first isolation of pure crystalline pyridoxamine and pyridoxal phosphates. In the last few years he and his colleagues, particularly Dr Robert Simpson and G. W. Rushizky, made major advances in our understanding of the interaction between basic oligopeptides and polynucleotides, particularly when applied to research on the chemical nature of chromatin.

Herbert Sober was, above all, a man of great balance and human warmth. He was universally respected by his coworkers and students over the years and maintained, throughout his professional life, a blend of vigorous interest in science and a rare ability to share his love, wisdom, and simplicity with family and friends alike.

announcements

Appointment

Alasdair D. Berrie, Officer-in-charge of the River Laboratory of the Freshwater Biological Association at East Stoke, Wareham, Dorset, has been accorded the title of Visiting Professor in the University of Reading.

Miscellaneous

Biogeography Study Group. At the annual conference of the Institute of British Geographers, this Group was formally constituted. It aims to foster the study and development of biogeography by discussion and field meetings, and by providing contact with those people working in related disciplines. A symposium is scheduled for September, 1975, to be held on the North York Moors. Further information may be obtained from: Dr L. F. Curtis, Department of Geography, University of Bristol, Bristol, UK; Mr J. A. Taylor, Department of Geography, University College of Wales, Aberystwyth Dyfed SY23 3DB, Wales; Secretary, Institute of British Geographers, 1 Kensington Gore, London SW7 2AR, UK.

Fractionation Services. The American Red Cross National Fractionation Center, supported by the National Heart and Lung Institute, is offering facilities to an investigator, for the pilot-plant or large-scale production of blood proteins, enzymes, membrane fractions and so on. Further information from: Dr M. Wickerhauser, Director, American Red Cross National Fractionation Center, 9312 Old Georgetown Road, Bethesda, Maryland 20014.

METASERV prize. The Institute of Metallurgists has organised a competition in Metallurgy with prize money totalling £200 (including a special student Prize). The closing date for the competition is July 31, 1975. Further details may be obtained from: *The Metallurgist* or The Institution of Metallurgists, Northway House, High Road, Whetstone, London N20 9LW, UK.

International meeting

April 27-May 3, **Stereochemistry**, Lucerne, Switzerland (Professor J. Dale, Department of Chemistry, University of Oslo, Blindern, Oslo, Norway).

No longer so much solid ground

A BETTER public understanding of science is an objective being pursued in many parts of the world at present. Committees are constituted to look at the interfaces between science, politicians and the media. Interviewers are despatched to ask the man-in-the-street whether he knows what electricity is, and if so, who told him. Sociologists are busy clipping newspapers and measuring science coverage to the nearest centimeter. And science journalists are being called on to explain why the popular press will run stories on cancer cures in preference to those on radiotelescopes. The driving force for all this activity is undoubtedly a widespread belief that the public is disenchanted with science, and the corollary that an improvement in the quality or quantity of public exposure might result in a better appreciation of the virtues of the pursuit of science.

The very existence of a broadly based public disenchantment must be questioned, the more so since everyone seems to believe in it these days. Ask someone at random what he doesn't like about science and he will probably say "the atomic bomb", or "pollution", or "spending so much money on going to the Moon". After a period of idolisation, scientists have to come to terms with the fact that, like politicians, economists, lawyers and industrialists, they now have to live in a world in which they face frequent criticism about events far too complex to have an identifiable source. This is hardly disenchantment, more an entry into a world in which cynicism is more common than trust, and it is difficult to see that any public relations campaign will succeed, or even that it should be attempted.

There are, however, two kinds of people whose perception of science we ought to worry about: the politician, because he may want to use our results and because he holds the purse strings, and the young student, because he has it in his power to provide or withhold the manpower. To the extent that any politician cares about science at present, a common complaint one hears is that scientists don't seem capable of proffering clear-cut advice. The schoolboy, more forthcoming, may say that science is too complex and offers no obviously profitable pastures these days. Here there is scope for a careful

examination of how the scientist is depicted.

The problem is that, in many minds, a nineteenth century image of the scientist still persists—there are even those within the community who lack sufficient curiosity about their profession to have perceived that the scientist can no longer be portrayed as a bearer of truth. This is not to say that scientists are bearers of lies these days, but it is to assert that the character of most science is now so complex, particularly when dealing with man's interactions with the world, and the purposes for which research is pursued are so varied, that any generalisations that a scientist makes in the literature (and few scientists are happy to let someone else do the generalising for them) are written not on tables of stone, but in chalk, with a good chance of being erased within the year. Scientific statements are falsifiable statements (even though few scientists have read Popper) and in their very nature many of them are indeed going to be falsified.

'Maker of falsifiable statements'—this is hardly a generally understood view of the scientist, and certainly not the kind of know-all image that scientists are often portrayed in the media as possessing.

Yet without stripping away much of the popular mythology surrounding the scientist and his conduct of science, confusion is bound to continue among those who have been led to believe that the scientist's generalisation, having got past a referee or two, is therefore worthy of exceptional respect.

Outsiders and prospective insiders often learn about the true nature of science (which, it must be said, is much more stimulating and exciting than it would be if scientists' pronouncements were only verifiable) by shrewd observation. But it would be better if they could acquire this information more directly. Any project to increase public understanding of science could well devote much of its energy, not to passing round more facts, but to building up, probably through case histories, an appropriate primer on the way in which science knows in part at any particular time—and doesn't always proceed in the most logical way to build on partial knowledge.

Turkey's flower powers

PETER COLLINS REPORTS

THE recent decision of the Turkish government to make trade in opium poppy "straw" a state monopoly is a logical step in the process of assuming complete control of the production and marketing of this crop. It should also reassure those interested people outside Turkey who were surprised, if not distressed, at the announcement some months ago that the ban on growing the opium poppy (*Papaver somniferum*) had been rescinded. In fact, the lifting of the ban, although said originally to have been suggested for political reasons, was almost essential if widespread distress, possibly starvation, were not to be inflicted on the many thousands of farm families for whom this crop provides almost the sole source of income.

The story of this latest phase in poppy cultivation in Turkey goes back to the beginning of the 1970s. At that time, the United States government, acutely aware of the threat of heroin addiction among its younger population, came to regard Turkey as the main source of the opium from which that drug is derived. Thanks largely to the work of the United Nations Narcotics Laboratory in Geneva, it is possible to establish the provenance of opium samples with reasonable accuracy but in any event there is ample other evidence to support this view, although only a small proportion of the world's total opium is grown in Turkey. Determined to deal with the heroin problem, the United States persuaded the Turkish government to prohibit all cultivation of the opium poppy, an announcement made somewhat dramatically at a meeting of the United Nations Commission on Narcotic Drugs in Geneva in 1972. Moreover, it is certainly true that, following the ban, there was a rapid decline in the amount of heroin coming on the market, not only in the United States but also in the Riviera, where there was at one time said to be a "heroin famine".

The Turkish ban was imposed on the understanding that the United States would provide the funds—estimated at \$35 million—for recompensing the farmers who were being deprived of their main cash crop, and for the very large research and development programme required to find alternative

crops or other occupations. In the event, while several million dollars were handed out as compensation, the crop-substitution programme never really got off the ground—a factor that may also have influenced the Turks in their change of mind.

The fact is that in those areas of Turkey where the poppy has traditionally been grown, almost no other cash crop will succeed. Poor soils, low rainfall, extremes of heat and cold make normal agriculture difficult, often impossible, over much of those provinces—Afyon, Burdur, Denizli, Isparta—in the south-western part of the Anatolian plateau. To the problems posed by soil and climate were added that natural resistance to change of any agricultural population, especially when that change was apparently being made to please a foreign power for whom in any event they had no particular affection. In fact, the difficulty of substituting new crops, and ideas amounting almost to a new way of life, for opium poppy cultivation has been known ever since the late 1950s when the UN Food and Agriculture Organisation (FAO) became involved in this type of operation in Iran; and the Americans, with their teams of willing but perhaps oversophisticated experts under AID, were even less successful than previous efforts in this direction. It seems almost as though AID was landed with a vast project which it would almost certainly

have rejected had it been suggested to it in the ordinary way of technical assistance.

At this early stage, the United Nations Division of Narcotic Drugs (the secretariat for the Narcotics Commission) was not involved, and indeed by the summer of 1973 it still had little idea of how the American crop-substitution project was progressing, although there were suspicions that things were not moving very rapidly. What seems to have happened next is that the then opposition party in Turkey held out the removal of a ban on poppy cultivation as part of its election programme. Rather unexpectedly, it found itself in power, and committed to implement its promise. Having effectively snubbed the Americans, the party went to the United Nations for advice. With the arrival of a UN mission in the poppy-growing areas, an unappreciated factor became apparent. It was already known that the situation in Turkey was very different from that in Iran, the other Near Eastern country with a major opium poppy problem. In Iran, opium has for centuries been smoked in the villages in the areas where it is grown. In Turkey the villagers do not smoke opium, but rather the importance of the poppy crop lies primarily in the seed, as the principle source of vegetable oil for the local population and, after extraction, of oil-cake for cattle feed. The rest of the plant is

A poppy field in Turkey: Daily Telegraph picture.

normally used for bedding for livestock. This is not to say that no opium was produced, but the poppy heads were lanced and the opium thus obtained sold, principally when a farmer needed extra funds at short notice, as for example for a wedding or a funeral.

The facts on which this UN 'discovery' were based had certainly been available to the Americans, since it was in examining their very full statistics that the mission was able to confirm what conversation with farmers and other local people had indicated: that there was little growing of the poppy solely as a source of opium. But the Americans had been so obsessed with the idea that 'Turkish opium becomes American heroin' that they had missed the real facts, and gone bull-headed for the complete and immediate prohibition of what was in fact the most important crop for perhaps 100,000 Turkish farmers. Faced with this situation, the Turkish government were to receive some \$35 million for the re-development of the areas affected.

The fact that opium production is not the main objective of Turkish poppy culture added a sound agro- and socio-economic argument to the government's decision to rescind the ban. What will happen now is that the poppy will continue to be grown as before, until the vital two weeks during which the capsules are ripening. It is at this time that, when opium is being produced, the

heads are lanced so that the opium latex can ooze out. It is a laborious business, because the grower must wait 10 to 12 hours before the hardened latex can be collected. Besides keeping several people busy for some hours, this is obviously a difficult process to conceal. It is at this period that an army of government inspectors will descend on the farmers to ensure that no lancing of capsules or illicit sale of materials takes place. Once the capsules have dried, the farmers will be able to collect the seed, both the yield and quality of which is improved when no lancing is carried out. The empty capsules and the upper parts of the stem—the 'poppy straw' of commerce—will later be collected by the government for processing to extract the morphine and codeine for the pharmaceutical industry. In this way opium and hence, heroin, is bypassed completely, yet the farmers will still have the rest of the plant for livestock bedding. Moreover, by setting up their own processing plant, the Turks will not only further reduce any chance of their raw materials getting into the illicit market, but will also acquire a lucrative state monopoly. A second UN mission has in fact only recently returned to Geneva after examining the financial and technological aspects of this further project.

On the ground, plans for putting the government's scheme into action have

been well advanced for some months. Farmers wishing to grow poppies must apply through defined channels, and their applications, with the area it is intended to cultivate, must be duly registered; the total area under this crop has been put at 20,000 hectares (about 45,000 acres) spread over the seven provinces in which it has always been grown. The fact that these poor soils give low yields is of little immediate interest to the government; what matters is that the livelihood of the farmers is assured at least at the previous levels, particularly if the Americans can be persuaded to release the remainder of the \$35 million to help stabilise the situation in the next few years.

It is realised, of course, that this system is unlikely to be completely watertight during the first season, although the UN in Geneva are quietly confident that the Turks will attain their general objective, namely to keep Turkish-grown opium off the world market. The new system will be far simpler and probably cheaper to run than the ceaseless pursuit of illicit opium traffickers, although obviously vigilance will not be relaxed there either. But the government announcement of January 17 makes it quiet clear that the severest measures will be taken against offenders—their harvests will be destroyed, their licences will be cancelled, and no further licence will be granted in the future. Offenders will also be subject to 'the relevant provisions of Turkish penal law'.

A system such as this, especially if it is rigorously enforced, should provide the necessary safeguards to reassure the Americans. Recent reactions from the United States show, however, that they remain unconvinced. One Senator has been quoted by the BBC as saying that it was 'obvious we will be inundated with heroin' now that the ban on opium poppy cultivation is lifted. This alarmist attitude, as reported by the BBC, betrays a complete lack of faith in the power of the Turkish government to control the situation. It may be that, nettled by the failure of their own huge project, the Americans do not credit the facts about Turkish poppy cultivation reported by the two UN missions. But if the Turkish control system goes as planned, no opium at all will be produced and once the proposed processing plant is in operation, in two or three years time, only drugs such as morphine and codeine will come from Turkey.

Whether American pessimism or Turkish confidence will be justified is perhaps anybody's guess, and will remain so until the critical weeks of the poppy seed—or opium—harvest in May this year. □

international news

SINCE energy research and development is a politically popular topic these days, the Ford Administration, which has been searching desperately for something politically popular to announce, has been making much of the fact that massive increases in federal funding for energy technologies were included in last week's budget. The amount has been variously reported as \$1,663 million, \$1,837 million, \$2,115 million, \$2,360 million and \$2,829 million—an array of figures which should further enrich the confusion over energy policy in the United States.

Energy research and development, it should be understood, can be defined in various ways, and various budget figures have been based on different definitions, hence part of the confusion. Another complication is the fact that budget figures are expressed in two different ways—obligations, which represent commitments to pay for grants or contracts although the actual expenditure may not take place immediately, and outlays, which represent the actual amounts of money which each agency will spend in a given year. As far as energy research and development is concerned, there is a considerable difference between total obligations and outlays, all of which makes it a bit difficult to compare what the Ford Administration is proposing to spend next year with what will be spent this year.

Nevertheless, the Office of Management and Budget (OMB), which produced President Ford's budget request, has made an attempt. It has come up with an analysis suggesting that, if Congress agrees to the proposals, obligations for energy research and development will increase from \$1,669 million this year to \$1,837 million next, whereas

Analysing the US energy budget proposals

by Colin Norman, Washington

outlays will increase from \$1,222 million to \$1,663 million over the same period. In addition, obligations for closely related environmental and basic research will increase from \$497 million to \$523 million and outlays on those activities will grow from \$367 million to \$452 million. The total growth in obligations being proposed for direct and related energy research and development is therefore a modest 10%, while the proposed jump in outlays is a spectacular 36%.

It is impossible to tell which individual programmes are being given priority from those figures, however. For that, it is best to turn to a different set of figures—the budget request for the Energy Research and Development Administration, as outlined by Dr Robert Seamans, ERDA's Administrator, to the House Committee on Science and Technology last week. Since ERDA is now responsible for the bulk of the Federal government's energy research and development, the ups and downs of the budgetary fortunes of its various divisions should provide a measure of which energy programmes are being favoured.

Seamans presented the committee last week with a table (see below) which provides details of the agency's budget request for next year. The table is expressed in terms of outlays, and although the total is greater than the

amount shown in the OMB's analysis for the entire federal energy research and development budget (the difference, an ERDA official supposed, probably arises because different things have been included in the summations) it provides further evidence of the dominance of nuclear power in the Administration's long term energy strategy.

Between them, reactor research and development, nuclear materials production and advanced isotope separation technologies—chiefly centrifuge enrichment—are set to receive \$1,118 million next year, which is an increase of \$236 million. Moreover, more than \$400 million is budgeted for capital expenditure on fission technologies, so the nuclear energy programme is again set to carry off more than half of the total energy research and development budget. The fact is unlikely to be accepted by Congress without demur, since there is a groundswell of opinion building up on Capitol Hill that non-nuclear technologies have been relatively neglected.

Although the figures proposed for such items as solar energy, geothermal power, and fusion look generous enough, the actual amounts indicated in ERDA's budget request are unlikely to satisfy most supporters of those programmes. The solar energy budget, for example, which is set to increase in ERDA from \$8.8 million this year to more than \$57 million next, should be seen in relation to Congressional appropriations for 1975 of \$50 million. Furthermore, a panel of experts told the Atomic Energy Commission two years ago that a minimum acceptable programme for solar energy development would involve expenditures of at least \$65 million in the 1976 fiscal year. Similarly, Congress authorised expenditures on geothermal energy in 1975 amounting to some \$44 million, yet the expenditure being proposed for ERDA in 1976 amounts to only just over half that. Although the National Science Foundation still has some programmes involving basic research related to solar and geothermal energy, Congress is unlikely to be satisfied with the amounts being proposed for next year in those areas.

It should also be noted that President Ford has formally proposed to reduce the amounts appropriated by Congress for ERDA in 1975 by some \$85 million; that proposal is reflected in the figures present in his budget. If Congress refuses to go along with that request,

ENERGY DEVELOPMENT PROGRAMMES	1975*	1976*	Change	
		\$ million		
Fossil energy development	195.0	311.3	116.3	59.6
Fusion power research and development	85.0	120.0	35.0	41.2
Fission power research and development	384.1	443.7	59.6	15.5
Nuclear materials production (less weapons activities)	445.2	596.1	150.9	33.9
Advanced isotope separation technology and laser fusion	53.1	78.2	25.1	47.3
Solar, geothermal and advanced energy systems development	34.9	108.6	73.7	211.2
Conservation research and development	16.7	32.2	15.5	92.8
Physical research	281.6	312.5	30.9	11.0
• Environmental and safety research	165.0	197.7	32.7	19.8
Plant and capital equipment for above	553.4	629.2	75.8	13.7
	2,214.0	2,829.5	615.5	27.8

*Fiscal years.

which is likely, then the totals shown in the table for 1975 would increase, the totals proposed for 1976 would decrease by a similar amount, and the total increase being proposed for the agency would shrink considerably.

In any event, Congress is likely to reorder the priorities in ERDA's budget a little, certainly by increasing non-nuclear appropriations and probably by reducing the amounts proposed for fission technology as well.

Even according to the OMB's analysis, however, the total amount of money that President Ford has proposed to spend on energy research and development in 1976 is more than double the total spent in 1974—\$1,663 million compared with \$833 million. A question that has not been raised too openly is whether that huge surge in funds can be usefully absorbed in such a short space of time. □

Mining company claims sea bed

from Peter J. Smith

THOSE who see exploitation of the ocean floor as a potential source of world conflict will take little comfort from a paid advertisement which appeared last week in *The Times*. For in the small-print Public Notices column, Deepsea Ventures Inc., of Delaware and Virginia, announced that "it has discovered and taken possession of . . . a deposit of North-east Pacific Ocean seabed manganese nodules."

The section of the sea bed over which the company claims "exclusive mining rights" is the area bounded by the latitudes 14° 16'N and 15° 44'N and longitudes 124° 20'W and 127° 46'W—a region lying in international waters between the Hawaiian Islands and mainland North America. Within this zone Deepsea Ventures intends to "develop, evaluate and mine the deposit and to take, use, and sell all of the manganese nodules . . . and the minerals and metals derived therefrom". As a form of "diplomatic protection and protection of investment" the company also "requests and requires [sic] states, persons, and all other commercial or political entities to respect the exclusive rights asserted".

Deepsea Ventures says that the validity of its claim is established "under existing international law as evidenced by the practice of States, the 1958 Convention on the High Seas, and the general rules of law recognised by civilised nations". In fact, the legal position is far less certain than that statement would suggest; the 1958 convention, for example, made no specific mention of any freedom to exploit the deep sea bed because at that time

NOT all of Pugwash's cries fall on deaf ears. A little known Swedish listener has offered to give substance to one of Pugwash's recent pleas: for an international institute to carry out advanced theoretical scientific studies into energy and ecology problems.

The pricked ears belong to Kjell Beijer, a Swedish businessman who last year set up the Kjell and Märta Beijer Foundation for the advancement of scientific research in Sweden. The foundation has decided that its first project will be the financing of the new institute, and is to donate Sk12 million (about \$3 million) over an initial period of 10 years for running costs and SK3 million for the construction of a building—to be attached to the Royal Swedish Academy of Sciences—in which the institute will be housed. The building should be ready by the end of 1976.

The institute will have close links with the academy in more ways than one. The academy is to be responsible for its establishment, and is at present working out the details of its organisation with the Royal Swedish Academy of Engineering Sciences. The main idea is clear: the institute should be shaped along the same lines as the Stockholm International Peace Research Institute (SIPRI). An international board of scientists will be responsible for the overall planning of the work, and a director (not yet appointed) will run day-to-day activities, make suggestions to the board about new projects and carry on his own research. The actual projects will

Architect's sketch of the Royal Swedish Academy of Sciences building showing how it will look when the new institute is attached (at left).

be carried out by 10–15 scientists, including guest researchers who will be invited to work on problems in specific areas. Four areas have been suggested so far:

- Surveys of energy resources, including new primary sources, such as solar, geothermal and fusion energy.
- Energy and economic development, taking into account the energy problems of developing countries.
- Energy and environmental effects, including the protection of the atmosphere against thermal, chemical and nuclear damage.
- Energy in relation to other resources, for example, minerals, water and food.

The focus will be purely theoretical. No experimental work is planned. This follows from the conception of the institute as a collector, analyser and disseminator of information to governments and the growing number of groups around the world who have started to take an interest in energy questions. The most visible of the institute's activities will be conferences, workshops, symposia and publications.

And when will work begin? With luck before the building itself is ready. But even if it takes until 1977 to work up full steam, the scientists can be sure that there will still be lots of energy problems left for them to solve.

Wendy Barnaby

exploitation was considered impractical.

In effect there is no international law on this matter—an omission which gives equally eminent authorities the opportunity to disagree about whether or not any form of occupation of the ocean floor is allowed. Last year's Law

of the Sea Conference in Caracas failed to resolve the question. It rather looks as though Deepsea Ventures has timed its announcement to concentrate the minds of the delegates when the conference reconvenes in Geneva next month. □

THE congress of ANZAAS—the Australian and New Zealand Association for the Advancement of Science—drew a crowd of 2,500 to the Australian National University campus in Canberra last month. Not as good a crowd as at some previous gatherings said the old-timers, and the spread-out facilities led to a feeling at times that we were the only ones there. Nonetheless, such an attendance was huge by British Association standards.

Many scientists find this sort of forum difficult to handle. For one thing there is uncertainty about who comprises the audience. For another, why launch the latest research result to a dimly discerning audience in Canberra when you can fly to London, Moscow or San Francisco to tell the specialists? This undoubtedly largely accounts for the relative poverty of the physical science section, but other sections gain by their very breadth of appeal. History, geography, education, industrial relations and economics all find a home in ANZAAS and, it is said, grow. But food science and nutrition attracted most attention this year. This could be seen partly as a reaction to the world food situation and partly as a move towards whole-animal (and especially whole-man) science, but maybe also as a reflection of an uneasiness amongst Australians that their diet encourages obesity. And all the signs are that obesity is on the increase.

The theme for the conference, "Science, Government and the People" was largely pursued through nine symposia inconveniently scheduled so that nobody could attend more than three. The quality was very uneven, but probably those who attended diligently emerged with a broader understanding of the scientific community and its external interactions. A national project for the public understanding of science 'warts and all' was one practical proposal that emerged.

It was encouraging that Mr Bill Morrison, the Minister for Science, and Mr Tony Street, Opposition spokesman, were so much in evidence and participated actively in the proceedings. Would that a few politicians in other countries made themselves visible and accessible in such gatherings, if only because most scientists view science policy as something remote and irrelevant and could profitably learn what the politicians think about it.

Police vans flanked the entrance to the Academy of Science for the symposium on scientific and technological research in universities and colleges of advanced education. Hardly an explosive subject, but the presence of Professor Roger Russell (Vice-Chancellor of Flinders University) guarantees a demonstration these days. Professor

Russell worked in the United States on various projects related to psychological warfare for the Department of Defense and according to some he still has involvements which they want him to disclaim publicly. There appeared to be about 20 in the audience of 200 who came to heckle and nearly twenty television technicians whose intrusive role in triggering confrontation was fairly obvious; but after some tough-mindedness from the chairman, Professor J. M. Swan, resulting in the ejection of four demonstrators, the

Australian diary

from David Davies
and Peter Pockley

Fly me

meeting was uneventful apart from some fairly conventional interruptions. Maybe three and a half hours on the binary system in advanced education was more than any demonstrator could bear. Maybe they feared for the safety of their tape recorders if ejected. Or maybe it was the fear of being dumped in the moat surrounding the academy.

With the exception of the Pharmaceutical Sciences Section which regularly brings a team of overseas experts to Australia for these congresses through direct funding by drug companies, ANZAAS meetings seldom attract contributors from overseas to present papers of international significance. It was therefore all the more notable that Dr R. J. Murgatroyd, Chairman of the British Meteorological Office's Committee on the Meteorological Effects of Stratospheric Aircraft (COMESA), chose ANZAAS as the venue for a major announcement.

Australia has been the scene of extensive public debate on the alleged deleterious effects of the SST aircraft, particularly Concorde. Various airlines want to fly it to Australia from Europe and America (the London-Sydney trip could be cut by half to 12 hours

or so). An environmental bandwagon against Concorde has had considerable political effect over the past three years. Despite an Academy of Science report which cautiously cast doubt on the validity of theoretical projections by American and Swedish chemists, the Australian government has so delayed confirming orders for Concorde that most people think the deal is off.

Dr Murgatroyd's conclusions were clear—several hundred Concorde would not reduce the stratospheric ozone concentration by more than 1%, 1,000 Concorde would cause a reduction of about 3%, and 2,000 Concorde about 6%. Because of their higher operating altitude (20 km, as against 17 km for Concorde) and their higher engine emissions by virtue of a greater size, American-designed SSTs could produce roughly twice the effect. Climatic changes brought about by Concorde would similarly be minute, several hundred Concorde resulting in a variation of less than 0.1 °C. Formation of condensation trails would be unlikely to lead to anything more than minor increases in stratospheric clouds, and these only in equatorial regions and polar areas in winter. All effects are well within natural variations (for example stratospheric ozone has been found to vary by $\pm 6\%$), and the effects of subsonic aircraft may be greater in some cases.

The conclusions of COMESA according to Dr Murgatroyd, are consistent with the results of parallel American and French government research programmes, the American research having now been published as well. The greatly increased confidence of their predictions is accounted for by several factors, all linked with the availability of massive and reliable data on natural atmospheric processes, engine emissions, numbers of aircraft, flight routes, photochemical reactions and mathematical modelling.

Dr Murgatroyd considers the ozone in the stratosphere to be under greater threat from the possible deleterious effects of freon gases from pressure pack sprays and refrigeration equipment. First rough calculations suggest a reduction of 1% in O_3 at present levels, but in 15 years the reduction could go up to 5%.

The campaign against Concorde and the fears about damage to the Great Barrier Reef by *Acanthaster planci*, the so-called Crown-of Thorns starfish, rank equally as the biggest single environmental issues raised in Australia. Over the past five years or so, the apparent southward march of the starfish along the 2,000 kilometres or so of the largest string of coral reefs in the world has retained the interest of public and politician alike. The campaign for direct action to "save the

reef" has been led by some zoologists in Queensland, and although nobody has doubted the existence of a real problem, there has been considerable disquiet among less vocal scientists regarding some proposed solutions (for example, direct killing of starfish *in situ*, using teams of divers) and the emotionalism which crept into the publicity.

Nonetheless, the Australian government established a special Advisory Committee for Research on the Crown-of-Thorns Starfish to administer a research fund. \$A330,000 (Aust) was allocated in the first three years of the committee's existence (1972-4), and the original limited programme has been extended for a further year with \$150,000. More government support went into an ambitious survey of 25 reefs in the Great Barrier Reef geological province last year, using ships and divers from the Royal Australian Navy. Mr Richard Kenchington, research fellow of James Cook University, Townsville, who co-ordinated the survey, reported at the ANZAAS Congress that the numbers of starfish on 14 of these reefs were negligible. This, however, has not led to complacency, for the threat to research areas covering the whole range of marine science, such as that at Heron Island, and the economically important tourist reefs is still keenly felt.

Mr R. G. Pearson, of the Department of Primary Industry, Queensland, reported some encouraging results on his surveys of the rate of regeneration of coral reefs after the 'wave' of starfish has passed. Soft corals appear to re-establish themselves in a few years. This kind of research and that concentrating on the largely unknown biology and behaviour of the species were strongly commended for future starfish research by a panel of influential scientists at ANZAAS.

Among other hard-hitting speakers, Dr Frank Talbot, Director of the Australian Museum, Sydney, said the starfish "plague" is not a real problem, is not man-induced and should not be supported by a special research fund. Others welcomed the strategic significance of the public support for the starfish research programme in that it focussed attention in Australia on the long neglected marine sciences and on the great ignorance of the Great Barrier Reef. Now that the ambitious Australian Institute of Marine Science is under way, the general consensus of speakers seemed to be that the days of a research programme relating to a single species and absorbing a substantial proportion of marine research funds should be numbered.

● The announcement at the congress of

THE most recent British Airways advertisements for Australia show a gnarled man (opposite) wearing a hat around the brim of which dangle a dozen corks on the end of pieces of string. The purpose of this hat has been widely debated in Britain, and the British visitor will find even more mystification when he lands at Canberra to be greeted by what appear to be royal waves from the locals. The explanation of both these phenomena is the ubiquitous bush fly, *Musca vetustissima*, and no tour of the capital is complete without a visit to the entomology division of the Commonwealth Scientific and Industrial Research Organisation (CSIRO) to find the latest on biological control of this pest.

Dr D. F. Waterhouse, director of the division, wrote in *Nature* in 1973 (246, 269) about the dung problem in Australia. Thirty million cattle each produce twelve dung pads a day, and the means of their disposal are on the whole lacking in Australia. Whereas in other countries various dung beetles get to work in their tunnelling and ball-rolling as soon as the dung hits the ground, in Australia it can sit there for years, eclipsing signi-

ficant areas of land, leading to grass that cattle won't eat and providing an ideal breeding ground for flies.

Gradually the problem is yielding. Sterilised imported dung beetle eggs from Africa have been used for several years to generate huge populations of coprids which have been spread around northern Australia with some success. It has become clear, however, that it is necessary to supply a variety of species (in Africa there are at least 2,000) if the attack is to be entirely successful.

And will the farmer accept an intrusion of scientists on his cow patch? Yes, says Dr Waterhouse, if things are done through the proper state channels.

Not all the division's work is unmitigated dung dispersal. There are new and highly successful techniques for eliminating insects from grain storage without resort to malathion. There are attacks on the skeleton weed by the use of fungi. There are genetic assaults on the sheep blowfly. There are even new ideas for fruit tree pruning. The returns on investment are potentially high as some pests cause tens of millions of dollars worth of damage every year.

the terms of reference for the Australian Science and Technology Council (ASTEC) does not guarantee the rapid formulation of Australia's first clearly enunciated science policy. The main danger to ASTEC is precisely that which afflicted the defunct Advisory Committee on Science and Technology, appointed by the last Liberal Government in 1972: the threat of imminent political change.

Since Mr Whitlam's Labour Party

was re-elected in May 1974, the government has lost its public support to a quite remarkable degree. Inflation hit Australia hard only in the past eight months and is now running about 20% a year. Unemployment has risen to a near-Depression level of almost 4%, an intolerable situation for a socially oriented Party. There is daily talk about whether the Opposition-dominated Senate will force another election this year, as they did last year

by refusing to pass the government's money supply plans. On the other hand, the Opposition itself is wracked by a leadership struggle, with, interestingly enough, the Liberals' last Minister for Education and Science, Mr Malcolm Fraser (a right winger), emerging as the strongest challenger to Mr Bill Snedden.

In the face of these running political issues, science still seems pretty small beer. The Minister for Science, Mr Bill Morrison, just made it into the ministry after the election in May 1974—he came 27th out of 27 in the elections to Cabinet by his parliamentary colleagues. It is not entirely surprising therefore that it took until two weeks before ANZAAS, and over two years after he was first elected to the ministry, for him to gain sufficient priority in Cabinet to present his first major submission relating to science policy. Some commentators, however, have felt that Mr Morrison has been content to let things drift for, apart from the consumer cause which he has espoused with some energy, he has seen little political advantage to be gained in science.

The two-year wait has been a frustrating one for those Australian scientists who had been looking to Labour for action. Labour had a science policy in its Party Platform for some time in contrast to the Liberals' steadfast refusal to acknowledge the very possibility of, or need for, a coordinated approach to science. The year 1974, however, brought forth a rash of documents and discussions which have led to the final formulation of ASTEC, and no interested party can now complain that their voice has not been heard. There are some, though, whose voice may have been heard but not heeded. Notable in this category must be the Department of Science whose heads can hardly be happy with the statements in the White Paper launching ASTEC which show that the department's role in recommending policy to the government will be subordinate to that of ASTEC.

Mr Morrison's major move towards gaining a consensus about a science council was the invitation to the OECD to carry out one of its independent surveys of science policy. This study, under the leadership of the redoubtable Dr Alexander King, was carried out early in 1974 and led to a preliminary report by the OECD and one of their "confrontation" meetings in Paris last autumn. Meanwhile, ANZAAS had established a Science Policy Commission under the chairmanship of Professor Sol Encel, a sociologist at the University of New South Wales, who is one of Australia's few professional students of science policy. Its report was published in the November

1974 issue of ANZAAS's journal, *Search*.

With some differences in detail and emphasis, both the OECD and ANZAAS recommendations converged on the need for a council to embrace not just traditional science, as favoured in the earlier discussions, but also technology, medicine and the social sciences. The Academy of Science also played an important role in influencing the final shape of ASTEC but, as is its wont, the academy worked more in private than in public.

It is impossible at this stage to assess the degree of acceptance by the Australian scientific community of the ASTEC arrangements. The White Paper was officially released to coincide with the start of the ANZAAS Congress, but the distribution was ineptly handled and few congress delegates even had sight of a copy before the major symposia at the congress where the issues involved were discussed. A meeting to discuss the ANZAAS report mustered a mere 70 in the audience.

But it is already clear that Mr Morrison's proposals (he claims to have largely written the White Paper himself with help from his staff—there is no evident love affair between the minister and his public servants) comprise a minor political victory in three areas, all of which will be welcomed by Australian scientists. These involve the terms of reference and powers of ASTEC to encompass not only science, but also technology, the medical sciences and defence science (within the limits of security). To the disappointment of some, ASTEC's role in relation to the social sciences is not at present intended to extend beyond the interaction of the social and natural sciences, as in multidisciplinary studies of complex problems.

The political victory comes in that funding of research and development technology, medicine and defence have come exclusively under ministries other than Science, and this has contributed substantially to the fragmentation and lack of direction in Australia's overall science effort. Proposals for the integration of these disparate elements will have to be formulated with great

bureaucratic and political skill by the members of ASTEC, and therein will lie a major test of its potential influence in the science scene in Australia.

The Labour Party's Platform had advocated that the members of a science council be elected by the scientific community; this has been abandoned in favour of the traditional method—appointment by the Minister, who significantly for the status of ASTEC will formally be the Prime Minister. ASTEC will be unusually sensitive to the quality of its first appointees, and further significant commentary on it may have to await that announcement.

● Gough Whitlam himself gave a paper at the 'Grand Symposium' on the final night. Recently returned from extensive foreign travels, he shared the platform with the Presidents of the Academies of Science, Social Sciences and the Humanities in an evening of remarkably good public speaking. His speech was mainly directed at the rationale behind the science policy White Paper, but he surprised the audience by taking the floor again after the main speeches to deal firmly with issues raised—particularly some questioning of his uranium policy and some remarks about trying to keep academics, particularly in the humanities, from emigrating. Professor J. Passmore (Academy of the Humanities) had been bemoaning the poor quality of Australian libraries and the great delays in the arrival of journals.

Nowhere on his travels, Whitlam said, had anyone suggested that the uranium should be kept in the ground, although he was fully aware of proliferation problems and hoped to "do something" about them.

On emigration, he professed no concern. Maybe the scholars move away but the practitioners come back to play, sing, paint and so on. Not quite the same thing, muttered the audience as they left, dazed that even a mild bit of politicking had entered their sedate arena. And there wasn't a glimmer of a response to Passmore's gentle suggestion that the government might air-freight journals from Europe and North America. □

Must new universities be poor relatives?

● In 1946 there were 25,600 students in six Australian universities. In 1972 there were 128,000 in eighteen. But there is a failure rate of 30% and many academics speak with concern of the quality of staff in some of the newer universities. If these universities are not to be seen as poor relatives, they face a long haul of consolidation. There could be a major role for CSIRO in this. The OECD report speaks of a need for greater mobility amongst Australian scientists and it may be that the new universities, armed with this report, should seek strengthening of their staff through more direct collaboration and exchange with CSIRO.

A searching look at Israeli science

from Nechemia Meyers

AN extraordinarily incisive and explosive 71-page report on the interaction between Israeli industry, science, universities and government was released this week by the Jerusalem-based National Council for Research and Development after being kept under wraps for two years. The report, submitted to the National Council for Research and Development (NCRD) in December 1972 by Dr S. Wald, a well known OECD economist and expert on science policy, notes that the country invests very substantial amounts in research and development (2.5% of its GNP) and that its research is of very high quality. Nevertheless, Wald charges, Israel's policy for research and development lags behind that of western Europe and North America "perhaps more than it did 20 years ago".

The factor primarily responsible for this situation, in Dr Wald's opinion, is an insufficient emphasis on applied research. "Israel," he says, "appears to be the last bulwark of the old faith which puts theory and pure science above practice and applications".

Wald caustically suggests that Israeli professors, to whom he attributes great influence, "may have greater respect for discovery than for development because few have had experience in development work and thus can hardly be expected to realise that the discovery of new material is sometimes intellectually less demanding than the discovery of methods to produce that material in tons and for an acceptable price".

Government ministries, Wald argues, have little more understanding of the situation. In the words of the report: "they act as if once a great 'discovery' is made its 'development' will be routine work and can more or less take care of itself".

Even industrial companies "have interiorised the prejudices of which they are the main victims", Dr Wald believes, adding that men who in Europe would be called "research directors" and in the USA "vice-presidents for research" are in Israel termed "development directors". This suggests that "nothing or almost nothing of their work would qualify as 'real' research".

Dr Wald reports on conversations with Israelis who link the country's single-minded dedication to pure research with Jewry's traditional emphasis on learning for its own sake. The image of Einstein, who changed the world and gained immortality with the stroke of his pen, was also invoked. This image,

Wald says, "has perhaps left a more disastrous mark on the minds of young people in Israel than in any other country".

Credit must certainly be given to the NCRD, which is part of the Prime Minister's Office, for publishing a document which declares: "No government in the Western World has so much concentrated economic and industrial power, yet none uses it so little to define and to achieve precise technological goals involving industry and universities".

It is perhaps not without significance that the document, which takes the government to task for failing to deal with questions of science and technology on the Cabinet level, was released only after the belated appointment (last month) of a Ministerial Committee on Science and Technology.

One goal of this new committee will certainly be to coordinate existing research programmes of government ministries which, Wald says, "to some extent still consider each other as competitors and not as complementary instruments of one and the same nation". His report cites the example of a project which the Ministry of Commerce and Industry approved on scientific grounds, but would not finance because telecommunications "belonged" to the Ministry of Posts and Communications (which at that moment had no applied research fund).

Marketing is much underrated in Israel according to Wald, who found it regarded "as a second-rate propaganda job", rather than as a suitable occupation for skilled scientists and engineers. The OECD economist also questions the Israeli tendency to look for large American corporations to serve as partners and marketing agencies for local industry. These big companies, he warns, are likely to view Israelis as very minor partners who can be dropped quickly if other considerations arise (a need to cultivate the Arabs, for example).

Dr Wald suggests that Israel should model her technological development programmes on those of small Western European countries like Holland, Switzerland and Denmark rather than on the USA. He points out that, like Israel, they have meagre natural resources and that their relative prosperity has been achieved by concentrating on the development of a few quality products, with which they are capable of competing on the world market. Israel's key products, he says, might come from the electronics and aeronautics industries, and more particularly from a few companies, like Israel Aircraft Industries, with sufficient turnover to finance a serious programme of research and development.

Western European countries accord

applied research and engineering higher prestige than they enjoy in Israel, Wald notes, mentioning in this context the fact that these nations sometimes create highly prestigious national academies of engineering science, a parallel to their science academies. Moreover, their universities are quick to meet local industrial requirements. When the Swiss watch industry was in trouble, Wald recalls, the university in Neuchâtel set up a faculty to train watch-making engineers "without worrying whether watch engineering was a recognised engineering profession, was a 'science' that could lead to publications or was represented at MIT".

Wald notes that Israeli professors have in recent years stressed their commitment to industrial development, but wonders if they are indeed prepared for a drastic change in science policy. The fact that Israeli industrialists still receive letters of recommendation from professors stating that a particular student is not quite good enough for PhD work but would make an excellent researcher in industry "speaks louder than public declarations", Dr Wald says.

With all his criticism, the OECD economist remains optimistic about Israeli's industrial future. "A visitor", Wald observes, "has the almost daily impression of an exceptional reservoir of will and talent which could be organised with more efficiency and profit. Many of the ingredients which make for a powerful industry-technology-science interface can be found in the country. Like pieces of a puzzle, they lay there—some fit together already, others are still in disparate order awaiting the hand that will push them together". □

First catch your bear

THE Soviet Ministry of Agriculture has drafted a special programme, within the framework of the existing international agreement, for the protection of Polar Bears. Accordingly, an expedition is shortly to leave for Wrangel Island, which has the largest bear colony in the Soviet Arctic.

The tagging of adult bears and their cubs is to take place in March and April, when the bears bring their cubs out to bask in the sun. The procedure, it is announced, will take the form of painting a number in red on the backs of the bears and the insertion of metal rings in their ears.

The *Novosti* press release announcing this expedition is headed optimistically "Polar Bears no longer threatened with extinction". A happy prospect for the bears—but perhaps less so for the painters and ear-ring fitters. One hopes that the expedition will be equipped with a supply of stun-guns. □

correspondence

Czech mathematician

SIR,—On January 10, 1975, a petition was submitted to the Czech embassy in the Netherlands, concerning the position of the Czech mathematician and computer scientist Professor Karel Culik. The petition was worded as follows:

"The undersigned mathematicians and computer scientists are deeply concerned with the present position of Professor Karel Culik. Although his work has done much for the world-wide renown of Czech mathematics he is at the present time prevented from taking part in normal scientific activity; he has no position in his own country and at the same time cannot obtain permission to accept the offers he has from universities in foreign countries. The undersigned strongly urge the Czech authorities that Karel Culik be allowed shortly to pursue his career as a researcher and a scientist."

The petition was initiated by the European Association for Theoretical Computer Science, and signed by 238 scientists from 12 countries.

Yours faithfully,

J. W. DE BAKKER

(Vice-President, European Association for Theoretical Computer Science),
Amsterdam, Netherlands

Consultancy

SIR,—Two correspondents (December 13 and January 17) have recently criticised the way in which university staff misuse the facilities at their disposal by carrying out consultancy work.

There are other ways in which university staff take advantage of their position, particularly their flexible hours of work. Many for example mark GCE examination papers, or act as GCE examination supervisors, or as tutors at Open University Summer Schools. For these duties they are either paid or receive generous expenses.

Yours faithfully,

DERRICK BAXBY

University of Liverpool, UK

Golden handshake

SIR,—You make the proposal (January 10) that the golden handshake is the solution to the job stagnation problem in British universities. As a younger lecturer (holding an appointment in dental biochemistry) I feel such a measure would only make the situation worse. Senior experienced staff

would be removed and this would only add to the administrative duties and frustration of younger colleagues at the most intellectually fertile period of their careers.

An alternative solution to the problem would be the introduction of opportunities for lecturers who wish to retrain for other professions in the middle of their careers, with financial assistance during this period of training comparable to their existing salaries. Those in their late thirties still have 60 to 70% of their active careers before them.

The people concerned are first-rate men and women, who have reached their present positions in a highly competitive and selective field. Prior experience in academic life could make an important contribution to a subsequent career in a different profession. For example, the experience and knowledge gained by a biochemistry lecturer would be an invaluable asset to someone subsequently studying medicine.

Mid-course retraining is already practised in industry; it could well offer the solution to the academics' problems too.

JOSIE A. BEELEY

University of Glasgow, UK

For those in peril

SIR,—Your correspondents in this series (October 18, November 22, November 29) do not distinguish clearly between the scientific and political aspects of pollution. Peter J. Smith's statement that "asbestos products (and thousands of other equally or more dangerous substances) are here to stay" is not a law of nature, it is a political statement. It indicates that we are prepared to pay, wittingly or unwittingly, with our own, or other people's tissues for the goods and services that these substances offer.

To be able to say under what conditions they are to stay, the scientists will have to tell us about the medical effects of existing pollutants in industrial environments and in the general environment, whether the effects are dose-related, how concentrations can be monitored, and how potential pollutants can be recognised—all difficult, expensive and time consuming problems. But the medical scientist cannot judge this—to him all avoidable tissue damage is totally abhorrent. 'Public opinion' has to decide how much discomfort or loss of years an individual

must pay.

How can the cost or risk for each pollutant be presented intelligibly for the public to judge its acceptability? Setting out the expected health effects, as for SO₂ and smoke, is one way. But concentration-time scales would incorporate commercial and political realities. LD₁₀₀ (concentration X for N years) is bad for business (and votes). A lower product for ill-health may be commercially acceptable in terms of lost man hours or compensation, but becomes less acceptable in the context of individual workers.

But the data must be sound. Unsound scientific or political activism could so limit industrial or daily activity that ill-health from pollutants could become replaced by poverty.

W. F. WHIMSTER

London SE3, UK

The economics of recycle

SIR,—In order to put recycle in a proper perspective (January 17), it is necessary to remember the following factors:

The future availability and price of key raw materials, as well as of oil, have been placed in doubt by the events of the past year. These events have emphasised the need to conserve our national resources. Recycle, or reuse of materials, is an important aspect of the proper management of these resources. It is, however, but one aspect and should be operating along with other measures such as improved design and reduction in waste both in manufacture and use.

Recycle is only viable for those materials which can be collected, reprocessed and made into products which can be sold at competitive prices. The problems are therefore basically technical and economic.

T. S. McROBERTS

Wolfson Recycle Unit,
Queen Mary College, London, UK

Nutrition

SIR,—I would be grateful if you would make it clear that the views expressed by Mr John Rivers in your article entitled "Between combine harvester and ribosome" (January 10) is an expression of his own views. The article should not be regarded as an official pronouncement of this institute.

Molecular evolution and the age of man

from John Maynard Smith

It is always intriguing when scientists with different backgrounds and training apply their different techniques to the same problem, and come up with totally different answers. This situation has now arisen in the study of human evolution. The traditional palaeontological approach suggests that the lines leading to man and to the great apes diverged at least 15 million years ago, and perhaps longer; biochemical evidence has recently been interpreted as showing that the time could not have been more than 5 million years.

At first sight, a comparison of proteins of different species seems just one more phenotypic comparison providing information similar in kind to that provided by a comparison of bones or teeth. This is not so. Knowing that the primary sequence of, for example, the insulin A chain in guinea pig and coypu differ by six amino acids, we can assert that at least six gene substitutions must have occurred in the relevant gene along the lineages leading from the common ancestor to the two species. A knowledge of the genetic code tells us that two of these substitutions could not have taken place in a single step, and hence that at least eight substitutions have taken place. Of course, these are minimum estimates. If the same changes have taken place in both lineages, or if some sites have changed several times, we shall underestimate the actual number of changes. This difficulty is a real one, but is probably less serious than might have been expected. A comparison of two proteins does enable us to estimate the number of gene changes that have occurred; we have no idea, even to an order of magnitude, of the number of gene changes responsible for the difference between the canine teeth of ape and man.

This method, combined with absolute dating from the fossil record, has led to some generalisations. Different types of protein evolve at very different rates. For example, cytochrome C evolves rather slowly, and fibrinopeptides (small peptides cleaved off fibrinogen when clotting occurs) very fast. A given class of proteins, however, evolves at a rather constant rate in different lineages. The exact degree of uniformity has been hotly debated, partly because of its relevance to the

'neutral' versus the 'selective' interpretation of protein evolution. The neutral theory asserts that most (though of course not all) amino acid substitutions which occur in evolution are selectively neutral. It is a prediction of this theory that the rate of evolution of a given class of protein should be uniform; hence the heat. Some striking exceptions are known; for example, insulin is remarkably uniform among mammals, except among hystricomorphs (a group of rodents which includes the guinea pig and coypu), which differ from each other and from other mammals by ten or more substitutions. A number of less striking discrepancies are known, but one is left with the impression of a surprising degree of uniformity of rate, at least when compared to morphological characteristics.

Unfortunately, it takes a lot longer to sequence a protein than to measure a bone (and longer still to discover the tertiary structure of a protein, which is a necessary first step if one is to make functional sense of the amino acid substitutions). This difficulty can be partly overcome by use of immunological techniques. A protein from species A is purified, and antiserum to it prepared. The 'microcomplement fixation' technique is then used to compare the extent of the reaction between the antiserum and the original protein from species A with the reaction with proteins from other species B, C, D and so on; it is a major convenience that the latter do not need to be purified. In this way, the 'immunological distance' between proteins can be measured. The technique has been extensively used in evolutionary studies by Sarich, Wilson and their colleagues. The protein used has been albumin; this is a large protein which evolves rather rapidly and so provides a lot of information. There is evidence, for albumin itself and for other proteins, that immunological distance measured in this way is linearly related to the number of amino acid substitutions. The relation is not exact, but it is close enough to make immunological distance a reliable guide to number of genetic changes.

The rate of evolution of albumin in different groups of vertebrates is apparently rather uniform (very approxi-

mately, two amino acid substitutions per million years, in a peptide 380 residues in length). As mentioned at the beginning of this article, the most controversial finding (Sarich and Wilson, *Science*, **179**, 1146; 1973) concerns the evolution of man. Three lines of biochemical evidence (immunological distance; electrophoretic comparisons of a number of proteins; direct sequence data on a few proteins) show that man and the great apes, and in particular, man and chimpanzee, are remarkably similar. These data suggest a time of divergence of perhaps three million years ago, and certainly not the 15–20 million years conventionally accepted. The obvious response has been that protein evolution has been particularly slow since the divergence, perhaps because of the long generation time. Wilson and Sarich retort that there is no evidence in favour of such a view. They argue that absolute dating of common ancestors from the fossil record is unreliable, but that the relative times of branching points are reasonably certain. For example, the common ancestor of man and tree shrew (*Tupaia*) is later in time than the common ancestor of these two and the bear or hyaena. Therefore, if protein evolution in the human lineage has been slow (because of long generation time or for other reasons), then the difference between man and bear should be less than that between tree shrew and bear. In fact, judging by immunological distance, the opposite is the case (although the effect is small). From this and other arguments, they conclude that protein evolution has not slowed down in the human lineage, and that the evidence cannot easily be reconciled with a divergence time greater than five million years.

This conclusion has not recommended itself to palaeontologists. Australopithecines, regarded as well on the way to being men, date back at least three million years. *Ramapithecus*, believed also to be on the human lineage, lived 12 million years ago. Dryopithecines, very similar to modern great apes, date back 20 million years. In the face of this direct evidence, it is hard to accept Wilson and Sarich's conclusion. We ought, however, to remember that *Ramapithecus* is, after all, only a few jaws and teeth, and that one school

of anatomists (noted, it is true, more for panache than perspicacity) still argue that *Australopithecus* is as close to the great apes as it is to man.

Equally surprising, but less controversial, conclusions have emerged from a comparison of albumin evolution in frogs and mammals. The rate of evolution of albumin has been very similar in the two groups, despite the much greater rate of morphological evolution in mammals (the first fossil frogs are 150 million years old). Wilson, Maxson and Sarich (*Proc. natn. Acad. Sci. U.S.A.*, **71**, 2843; 1974) have compared the albumins of 31 pairs of mammal species and 50 pairs of frog species which can produce viable hybrids. The average immunological distances are three and 36 respectively, implying that a tenfold greater degree of differentiation in protein structure is compatible with hybridisation in frogs than in mammals. The authors discuss the possibility that this is because of immunological reactions between mother and foetus in mammals, but give reasons for preferring an alternative explanation. They suggest that hybrid embryos die because of differences in gene regulation between the parental species, and that, relative to evolution of structural genes, gene regulation evolves more rapidly in mammals, associated with their more rapid morphological change. In a later paper (*Proc. natn. Acad. Sci. U.S.A.*, **71**, 3028; 1974) the same authors point out that chromosome evolution (as judged by changes in numbers of chromosomes and of chromosome arms) has proceeded more rapidly in mammals than in frogs and suggest that structural changes in chromosomes are associated with changes in gene regulation.

Decomposition in peatlands

from Peter D. Moore

MOST ecosystems in which production is in excess of respiration and decomposition accumulate the surplus energy-rich material as living biomass; peatland ecosystems are peculiar in that their excess is deposited as litter and accumulates as peat. In some peat-forming ecosystems, such as reedswamps, net primary production is high, but in those exhibiting the highest rates of peat accumulation, primary productivity is quite low. In such instances it is reasonable to assume that peat accretion results from a depressed decomposition rate rather than an inflated productivity.

Because mires hold many attractions for biologists concerned with the evaluation of energy and dry matter budgets for ecosystems, and also because peat is

Sphagnum magellanicum branch leaves, convex surfaces showing hyaline cells with supporting bars of secondary wall material and bordered pores. 1, green, living leaf taken from top 0.5 cm of plant; $\times 560$; 2, leaf taken from peat at 10 cm depth, showing partial decomposition of hyaline cells; $\times 460$.

an important natural resource in several countries, it is not surprising that a number of attempts have been made to develop mathematical models of peat-accumulating systems. The efficiency of any ecosystem model is limited by the reliability of the raw data used in its construction and, in the case of peat-forming systems, the most elusive information is that related to decomposition.

It is usually assumed that the loss of organic matter decreases exponentially with time (for example, Gore and Olson, *Aquilo Ser. Botanica*, **6**, 297; 1967). Although such an assumption is reasonable, its confirmation, and a precise knowledge of long-term decay rates for different materials, are extremely difficult to obtain. Clymo (*J. Ecol.*, **53**, 747; 1965) approached the problem by burying nylon mesh bags containing known quantities of *Sphagnum* moss at various depths in the peat. He demonstrated that losses were far higher in the superficial layers of peat than from deeper down, where conditions were permanently anaerobic. The disadvantage of such a method is that in natural circumstances the material entering the anaerobic zone would have already undergone some degradation during its period in the upper peat layers; on this basis one might expect even lower levels of anaerobic decomposition than Clymo's data suggest.

Direct observations on bracken decomposition over a period of years led Frankland (*J. Ecol.*, **54**, 41; 1966) to believe that the course of decomposition was essentially linear, and Reader and Stewart (*Ecology*, **53**, 1024; 1972) have therefore used this assumption in their model of peat accumulation in Canadian muskeg. They use decay rate figures from various plant materials which were exposed in bags for a period of a year. But the apparently linear decay observed by Frankland may have proved to be exponential if observation could have been continued over very much longer periods of time, and the assumption of linear decay is not generally favoured.

Two recent studies of peatland decomposition processes have concen-

trated on microscopic and microbiological examination of peats in order to gain some indication of the nature and rate of the decay process. Dickinson, Wallace and Given (*New Phytol.*, **73**, 107; 1974) have examined peats from the Florida Everglades and used three different methods for determining microbiological activity at different depths. They examined and counted the microorganisms present; they washed, plated and incubated peat samples; finally, they incubated samples from freshly exposed peat surfaces. Direct counts showed large numbers of microorganisms at all depths, but it is possible that the bulk of these were dead. The other two techniques showed a strong concentration of viable organisms within the surface layers of peat, as Clymo's work had suggested for *Sphagnum* peats. Once again, the inference is that the bulk of decomposition occurs in the superficial peat horizons.

An alternative approach has been used by Dickinson and Maggs (*New Phytol.*, **73**, 1249; 1974), who observed the results of decomposition on *Sphagnum* leaves by both light microscopy and scanning electron microscopy (see figure). They devised scores for different degrees of degradation and made estimates of the proportion of *Sphagnum* leaves in each condition at various depths down to 30 cm. Decay was considered to be due to the activity of microflora rather than fauna. Readings were taken at only four levels, making it difficult to discern any precise pattern of degradation with depth; however it would seem that about 20–30% of *Sphagnum* leaves had undergone some degradation at 16 cm depth and about 30–40% at 30 cm depth. Without information about accumulation rates of peat during the time that this 30 cm of peat had built up, it is impossible to infer from these data the precise pattern of decay processes. If, for example, peat accumulation has been fast in the past but is now slowing down it would be possible for material from deep in the peat to be better preserved than that near the surface.

Ultimately the method of Clymo and

Reddaway (*Moor House Occasional Papers*, No. 3; 1971) is likely to prove the most helpful for production ecologists concerned with peatland decay rates. They collected gaseous output from a peatland surface and assessed the flux of carbon dioxide and methane; they also measured organic losses in solution. The gaseous measurements can be considered as the respiratory products of producer, consumer and decomposer organisms from a complete vertical column of the peatland system. Their figures indicate that overall dry matter surplus (available for peat formation) in a Pennine blanket bog varies between $1 \text{ g dm}^{-2} \text{ yr}^{-1}$ on hummocks to $2.7 \text{ g dm}^{-2} \text{ yr}^{-1}$ on *Sphagnum* lawns. In spite of difficulties in measurement and the high variability of data with surface flora and microtopography, this still represents the most promising approach to the measurement of the respiration and potential growth rates of bogs.

Total reconstitution of *E. coli* 50S ribosomes

from a Correspondent

RECONSTITUTION of the *Escherichia coli* 30S ribosome from its constituent RNA and protein has been well established for several years (Traub and Nomura, *Proc. natn. Acad. Sci. U.S.A.*, **59**, 777; 1968), but total reconstitution of the corresponding 50S particle has proved a much tougher nut to crack. A reassembly procedure was described by Maruta, Tsuchiya and Mizuno (*J. molec. Biol.*, **61**, 123; 1971) using proteins liberated by the action of ribonuclease II, but so far no report has appeared of a successful repetition of this result. 50S ribosomes from *Bacillus stearothermophilus* have been reconstituted (Nomura and Erdmann, *Nature*, **228**, 744; 1970) by taking advantage of the higher thermal stability of ribosomes from this organism, but this of course is not so useful since most of the biochemical and genetic information concerning ribosomes has been accumulated from *E. coli*. Hitherto, biochemists have had to content themselves with the 'partial reconstitution' method for *E. coli* 50S ribosomes. This was first reported simultaneously by Staehelin and Meselson (*J. molec. Biol.*, **15**, 245; 1966) and by Hosokawa, Fujimura and Nomura (*Proc. natn. Acad. Sci. U.S.A.*, **55**, 198; 1966) who both showed that protein-deficient 'core' particles could be reassembled to active 50S ribosomes. Now, however, the total reconstitution of *E. coli* 50S particles from protein and RNA has been achieved, by a two-step incubation procedure, and is reported by Nierhaus and

Dohme in *Proc. natn. Acad. Sci. U.S.A.* (**71**, 4713; 1974).

Nierhaus and Dohme began by finding out how many proteins could be removed from the 50S particle before the resulting core particle became unable to regain its activity in the partial reconstitution procedure. Activity was measured both by the poly(U) assay, and by the 'fragment assay' for polypeptidyl transferase. They found that whereas 4 M LiCl cores could still regain activity, 5 M cores (containing only five proteins) had largely lost this ability, and 6 M cores (with only two proteins) could not be reconstituted at all. The obvious next step—a stepwise reassembly of 23S RNA to a 4 M core particle, and thence to a 50S ribosome—was not successful as judged by the fragment assay, although some activity in the poly(U) assay was recovered. Nierhaus and Dohme rightly interpreted this failure as an indication that the ionic conditions of the partial reconstitution procedure were not ideal for the early stages of total reconstitution.

They therefore mixed 23S RNA, 5S RNA and total protein, and investigated the effect of various incubations prior to the normal partial reconstitution. By optimising the conditions they arrived at a two-step procedure in which the isolated ribosomal components were first incubated together for 20 minutes at 40°C in 4 mM magnesium, 400 mM ammonium at pH 7.2, followed by the partial reconstitution incubation of 90 minutes at 50°C in 20 mM magnesium, 400 mM ammonium. This gave particles with a remarkably high activity, that is to say 80–110% in the poly(U) assay, and 40–60% in the fragment assay, as compared with native 50S sub-particles. Notably, no requirement for 30S particles or polyamines in the reconstitution mixture was observed. Phenol-extracted RNA and acetic acid-extracted proteins were used in the procedure, in order to ensure that the RNA fraction was entirely free from protein and the protein fraction entirely free from 5S RNA. This can therefore be regarded as a genuine total reconstitution, and should prove as advantageous to the understanding of the 50S particles as the corresponding reconstitution has already proved to the 30S. Detailed 'assembly mapping' of the 50S particle should now follow without too much difficulty.

Pituitary neuropeptides and behavioural processes

from A. Dickinson

THE idea that pituitary neuropeptides can influence behaviour by a direct action on the central nervous system is

a recent one. These effects of pituitary hormones seem to be distinct from their well known actions on target tissues such as kidney and adrenal cortex; they resemble rather the actions on the CNS of steroid hormones secreted by endocrine target tissues.

The relation of pituitary neuropeptides to learning processes was one of the topics discussed at the fourth winter school of the European Training Programme in Brain and Behaviour research (January 4–11). Some of the strongest evidence for a direct action on the CNS comes from the work of the Utrecht group on the effects of adrenocorticotrophic hormone (ACTH) and related peptides on avoidance behaviour. In their experiments an animal is required either to make some response (active avoidance) or to refrain from responding (passive avoidance) in order to avoid an electric shock. They showed previously that injections of ACTH restored the deficit in active avoidance induced by hypophysectomy and prolonged active avoidance in intact animals during extinction. ACTH also improves passive avoidance acquisition. The important finding is that these behavioural effects seem to be independent of the adrenocorticotrophic activity of ACTH since the injection of ACTH 4–10, a fragment of the ACTH peptide chain which has no adrenocortical stimulating activity, produces comparable changes in avoidance behaviour.

Dr B. Bohus's report on this work made it clear that the facilitatory influence of ACTH was only seen while the hormone was present in the body. It was therefore suggested that the primary central effect of ACTH is to increase the general arousal or motivational state of the animal. Such a general effect is in line with biochemical studies reported by Dr W. H. Gispen (Institute of Molecular Biology, Utrecht) showing that the behaviourally effective fragments of ACTH seem to increase the incorporation of labelled leucine into almost all brain stem proteins of the rat.

Dr J. A. Gray of the University of Oxford reported a complementary series of experiments using learned appetitive responses rather than avoidance responses. After training approach responses by positively reinforcing them with rewards such as food and water he extinguished the responses by withdrawing the reward and found that ACTH 4–10 prolonged such extinction. Though at first sight his results seem to be comparable to those of the Utrecht group, it is not clear that the interpretation given above for the Utrecht results will explain those of Dr Gray. Withdrawal of a reward engenders emotional arousal such as frustration; such aversive arousal actually

helps to produce extinction and an ACTH-induced increment in arousal might therefore be expected to shorten extinction of a positively reinforced response while prolonging the extinction of avoidance behaviour.

Dr Gray has provided further evidence that ACTH attenuates the emotional responsiveness of an animal as measured by positively reinforced responses. Tranquillisers such as sodium amylobarbitone seem to produce the same behavioural effects during the extinction of these responses as exogenous ACTH. Furthermore, Dr Gray has shown that the ACTH 4-10 fragment increases the threshold for driving a specific electrical rhythm of the hippocampus (the theta rhythm) from the septum in the same manner as sodium amylobarbitone. Previous Oxford work has implicated this system in the mediation of the behavioural effects of nonreward.

A second pituitary hormone with interesting behavioural effects is vasopressin. The Utrecht group has shown that this neuropeptide and its analogues without antidiuretic or pressor action have effects similar to those of ACTH on avoidance behaviour. They differ from ACTH in having an influence which lasts longer than their presence in the body. Dr Bohus suggested that vasopressin influences memory processes by affecting the consolidation or retrieval of learned responses. Using a passive avoidance task in which rats learned to suppress a response in one trial, he reported that animals with a lack of vasopressin through hereditary hypothalamic diabetes insipidus showed good retention if tested immediately after training but not if testing was delayed for three or twenty-four hours. If registration and storage-retrieval processes really can be distinguished using this neuropeptide, it may provide a powerful tool in the analysis of learning and memory.

In the study of the pituitary neuropeptides, psychological theory meets fruitfully with the other neurosciences. The effects of exogenous ACTH on the performance of learned tasks, effects which do not fit easily into the current behavioural analyses of these tasks, provide an important guide for revising both behavioural theories and concepts about the sites and modes of action of neuropeptides in the CNS.

Chilling statistics on Cyprus

from Peter J. Smith

THE sheeted diabase unit of the Troodos complex in Cyprus is a complicated geological feature whose stratigraphically central section is formed completely of dykes intruding other

dykes. The unit as a whole has an exposure in the east-west direction of more than 70 km, although the individual dykes, which generally strike north-south, range in width from a few metres to only a few centimetres. The periods between dyke injections were apparently sufficient to allow the previous dykes to cool, so that each new dyke was chilled against those into which it was intruded and thus has finer-grained or cryptocrystalline margins. But as many of the dykes are intruded by later ones, they may have been split several times, forming apparently marginless dykes which are in reality merely the central parts of once complete intrusions. And if that is not enough to cause confusion, some dykes intruded up the margins of previous dykes, so that the later dykes were chilled against the chilled margins of the earlier ones.

What is the origin of this remarkable structure? The answer to that question would be interesting enough if the diabase unit were only of purely local significance. But the Troodos complex is, of course, an ophiolite suite comprising ultramafics, gabbro, sheeted dykes, pillow lavas and deep sea sediments—a feature widely believed to represent ancient ocean floor. If the origin of the diabase unit could be determined, the result would give by implication the origin of the whole interrelated complex; and geologists would be sure at last whether or not they could claim access to ocean floor without the need for deep ocean diving.

The answer most geologists would welcome would be proof that the diabase dykes were injected at, or close to, an oceanic spreading axis. But as Kidd and Cann (*Earth planet. Sci. Lett.*, **24**, 151; 1974) point out, a structure composed entirely of dykes could be produced in two other ways—by random injection throughout the whole structure (that is, with a zone of intrusion much wider than that implied by seafloor spreading) or by the coalescence of dyke swarms from individual volcanoes.

Fortunately, however, the three models do not predict the same detailed dyke swarm structure. Consider the case of ideal seafloor spreading, in which the width of the zone of intrusion is infinitely small and in which each new dyke intrudes up the centre of the preceding one. On either side of the intrusion zone the oceanic crust will comprise entirely half-dykes, each having a chilled margin on the side away from the intrusion zone. In other words, on each side of the intrusion zone the magnetic vectors within the chilled margins will all lie in the same direction (they will be all 'one way') and the degree of 'one way chilling' will be 100%.

A hundred years ago

THE *Kölnische Zeitung* of Feb. 7 contains an abstract of a paper read by M. G. Wex, at the Geographical Society of Vienna, on the decrease of water in rivers and sources. The author states that the results of his observations tend to show the constant decrease of the rivers of Germany and the increase of seas. It appears from them that the levels of the German rivers are now much lower than they were fifty years ago; viz., the Elbe 17 in., the Rhine 24.8 in., the Oder 17 in., the Vistula 26 in., the Danube 55 in. As a reason for this decrease, the author gives the progressing devastation of forests, which causes a decrease in the atmospheric moisture they attract and convey to the soil and thence to sources. from *Nature*, **11**, 314; February 18, 1875

In any real spreading system, complete 'one-way chilling' will never be achieved because the intrusion zone will have a finite width and the splitting of previous dykes will not be as regular as in the ideal case. Nevertheless, as long as the intrusion zone is not too wide, some of the dykes will have been intruded close enough to the centre of injection for them to have been split by subsequent injections; and in such a case the degree of one way chilling, though far from 100%, should be significantly greater than zero. It is this statistical point which should enable the seafloor spreading model to be differentiated from the other two. Where intrusion takes place throughout the whole dyke region or where it is derived from several discrete volcanic centres, there is no single effective centre of injection and thus presumably no bias in the chilled margin directions.

Kidd and Cann have now applied these ideas by taking a number of well exposed and widely scattered sections within the Troodos dyke unit and measuring the directions of chilling of an odd number of margins within each section. Because the number of chilled margins within each section is always odd, there is bound to be an excess of margins in one direction or the other (east or west in this case because the margins trend north-south). But whereas the seafloor spreading model would predict a significantly greater number of sections with an excess in one direction rather than the other (the one direction being that away from the spreading centre), the two other models would predict no such imbalance.

In practice, the statistical bias is confirmed. Out of 23 section transects covering 41 chilled margins each, 19 transects (TRE) showed a preponderance of margins chilled to the east over margins chilled to the west and 4 transects (TRW) showed a preponderance the opposite way. The chance of obtaining such a bias from a system which actually contains equal numbers of TREs and TRWs is less than 1 in 200. This suggests that the statistics reflect a real physical effect, namely, that the Troodos dyke unit was produced as part of the seafloor spreading process. This conclusion is further supported by the number of chilled margins actually in excess within each transect. For transects with margins predominantly to the east the average number of margins in excess within each transect is 2-3, whereas for transects with margins predominantly to the west the corresponding figure is only 1.

Finally, since the predominant chilled margin direction is the direction away from the spreading centre, it follows from the data above that the spreading axis should have lain relatively to the west of the Troodos complex. It is necessary to say 'relatively' here because Moores and Vine (*Phil. Trans. R. Soc., A268*, 443; 1971) concluded from palaeomagnetic evidence that the complex has rotated through 90° in an anti-clockwise direction since it was formed, which implies that the dykes within the diabase unit were originally intruded in an east-west direction and that any spreading axis would have lain to the north. But although the orientation of the supposed spreading system is important, it is far more important for the time being to show that spreading took place at all. The simple, but elegant, piece of work carried out by Kidd and Cann provides further evidence that it did.

Copernicus and X-ray astronomy

from A. C. Fabian

THE Copernicus satellite launched in 1972 carries an 80 cm ultraviolet telescope-spectrometer from the Princeton University Observatory measuring interstellar absorption lines superimposed on stellar spectra. The small companion X-ray package from the Mullard Space Science Laboratory at University College, London, contains three grazing-incidence telescopes and a collimated proportional counter of about 15 cm² aperture. Both sets of instruments are pointed to the same location in the sky to fractional arc second accuracy by the inertial guidance system. Thus the ultraviolet telescope sometimes observes X-ray sources, and the X-ray systems spend

some of the time viewing hot stars.

In spite of this apparent clash of interest, much of the work with the X-ray package has depended upon the Princeton telescope. Fifty per cent of the light incident on the Princeton spectrometer is used in a fine error sensor to provide the primary pointing control for the satellite and a stellar reference system for the X-ray experiment. The resultant accurate pointing has allowed maps of supernova remnants and clusters of galaxies to be made. Scans of a number of X-ray sources in our Galaxy and the Large Magellanic Clouds have enabled their positions to be pinpointed within a few arc minutes. Identification with optical, radio or infrared counterparts is proceeding.

The failure of two of the X-ray telescopes in July 1973, owing to a jammed shutter blocking the light paths, has caused mapping operations to cease. Nevertheless, the collimated proportional counter which operates over a 2.5-10 keV range has not been idle. It is well known that the binary X-ray sources are highly time variable. The stable platform provided by Copernicus has allowed careful studies to be made of some of these X-ray binaries. The data so obtained are superior to those from scanning instruments such as *Uhuru* on time scales exceeding several minutes, owing to this accurate pointing. The larger area X-ray detectors on the recently launched Ariel-5 that view along the spin axis also enjoy some pointing stability, but drift of the spin axis will introduce uncertainties.

Source identifications can still be made through correlated X-ray and optical or infrared observation. Lunar occultations also provide a powerful technique, and have been successfully applied from Copernicus to a galactic centre source, GX5-1 and the Crab nebula. The motion of the satellite allows several passages of the Moon across these sources to be observed.

Many more X-ray observations have been proposed for 1975. At least one complete 'on'-state of the 35-d cycle of Hercules X-1 will be followed. This enigmatic binary system has been intensively studied optically over the past two years but the mechanism behind its 35-d cycle is still unclear; complete and accurate X-ray data are lacking. Several other binaries and suspected binaries will be monitored for extended periods. The tight schedules of the other X-ray detectors in orbit do not permit extended study of particular objects because of the need to conserve stabiliser gas in the case of UK-5 and the viewing constraints for the ANS. It is hoped that the X-ray observing programme of Copernicus will continue, for there is no lack of sources wanting investigation.

Nuclear spectroscopy

from P. E. Hodgson

STUDIES of nucleon transfer reactions have long been established as one of the most powerful nuclear spectroscopic techniques. The angular distribution is characteristic of the angular momentum transfer L and the magnitude of the cross section is a measure of its single-particle strength. If the target nucleus has spin zero and the transferred particle is initially in a state of zero orbital angular momentum the spin of the final state is simply given by the vectorial sum of the relative orbital and spin angular momenta in the transfer process. For a (d,p) reaction, for example, $J=L+\frac{1}{2}$ giving $J=L+\frac{1}{2}$. Thus a $L=2$ transfer can go to a $J=3/2$ or to a $J=5/2$ state. The ambiguity in sign can often be resolved from the known systematic behaviour of single-particle states but in other cases it remains a difficulty. Measurement of the polarisation of the outgoing proton together with distorted wave calculations or a simple comparison with the proton polarisations in reactions leaving the residual nucleus in states of known spin resolves the ambiguity, but is time consuming.

It has however proved possible in some cases to resolve the ambiguity by examination of certain features of the differential cross sections and it is found that they are characteristic of $J=L+\frac{1}{2}$ or $J=L-\frac{1}{2}$ final states. Such features are sometimes difficult to reproduce by distorted wave calculations but nevertheless can be used as empirical guides provided that they can be calibrated by studies of transitions to states of known spin.

These J -dependent effects, as they are called, are sufficiently distinctive to be used with confidence only for particular reactions in restricted energy ranges, so it is always valuable to find new circumstances or new reactions that display them prominently. Two recent papers have provided evidence of this type.

In the first paper, Kong-a-Siou and Chien of Michigan State University (*Phys. Lett.*, **52B**, 175; 1974) measured the angular distributions of several $L=3$ transitions in the (p,d) reaction on ⁶¹Ni and ⁶²Ni at 40 MeV and found a very stable J dependence over a range of intensities and excitation energies. Some of their results are shown in Fig. 1, and it is clear that the angular distributions fall sharply into two classes, one characteristic of $J=L-\frac{1}{2}=5/2$ and the other of $J=L+\frac{1}{2}=7/2$, and that in each case the data fall quite definitely on one or the other. The data for ⁶²Ni(p,d)⁶¹Ni thus allow the spins of the states of ⁶¹Ni to be determined.

The results for ⁶¹Ni(p,d)⁶⁰Ni to states

Fig. 1 Differential cross sections for the $^{61}\text{Ni}(p, d)^{60}\text{Ni}$ and $^{62}\text{Ni}(p, d)^{61}\text{Ni}$ reactions. The solid and dashed lines are smooth curves through the experimental data points of the known $f_{5/2}$ and $f_{7/2}$ transfers to the states at 0.067 and 3.30 MeV in ^{60}Ni . All the cross sections follow closely one curve or the other.

of known spins 2^+ , 4^+ and 3^+ respectively show angular distributions characteristic in each case of quite pure $J=5/2$ transfer. For the 4^+ state, only $L=3$ transfer is allowed by the conservation of angular momentum and of parity, but for the 2^+ and 3^+ states both $L=1$ and $L=3$ transfers can complete. The data show that only $L=3$ is present and this can indeed be understood by shell-model calculations.

The second paper, Kemper *et al.* of Florida State University (*Phys. Lett.*, **52B**, 179; 1974) report a study of the relatively unfamiliar (^7Li , ^6He) reaction that shows marked J -dependent effects for reactions to d and f states. For this reaction the transferred proton comes from the $p_{3/2}$ orbit in ^7Li so that the vector equation for the angular momenta is $3/2 + l = J$, where l is the orbital angular momentum of the transferred proton and J the spin of the final state. If for example $J=3/2$, then l can be 0, 1, 2 or 3. If the final state has orbital angular momentum L , then J can be $L \pm 1/2$ and the possible values of l are $l=L$ or $L \pm 1$. The relative proportions of these that contribute are given by the Racah coefficient

$W(L, J, 1, 3/2; 1/2)$ and it turns out that the components $l=L$ and $l=L-1$ are much more important for the states with $J=L+1/2$ than for those with $J=L-1/2$.

This is shown clearly in Fig. 2 by the angular distribution for the $^{24}\text{Mg}(^7\text{Li}, ^6\text{He})^{23}\text{Al}$ reactions at 34 MeV to $d_{3/2}$ and $d_{5/2}$ states of ^{23}Al . The curves show separately the distorted wave calculations of the contributions to the two cross sections, and it is found that the reaction to the $J=3/2$ state ($J=L-1/2$) is nearly all $l=3$ with very small contributions from $l=1$ and 2, whereas for the reaction to the $J=5/2$ state the $l=1$ and 2 components are relatively much more important. Since the contributions of different l have markedly different angular distributions this gives a difference between the cross sections for the reactions to the $J=3/2$ and $J=5/2$ states, and this can be used to distinguish between them.

Reactions like this are only just beginning to be studied in detail, and it is likely that other types of J dependence will be found and that they will prove powerful tools in nuclear spectroscopy.

Fig. 2 Differential cross sections for the $^{24}\text{Mg}(^7\text{Li}, ^6\text{He})^{23}\text{Al}$ reaction to $d_{3/2}$ and $d_{5/2}$ states in ^{23}Al . The curves are distorted wave calculations and show the difference between the relative contributions from $l=1, 2$ and 3 transfer in the two cases.

Palaeoscience and the modern world

from J. A. Taylor

WHAT relevance have the palaeosciences to the interpretation and solution of the environmental problems of the modern world? Judging by the meagre support given to some of the palaeosciences (notably palaeobotany, palaeopedology and palaeoclimatology) by the Natural Environment Research Council, the answer would be "precious little". Yet the improved techniques of the palaeosciences are finding uses in present-day ecological studies, thus bridging the gap between the study of ancient and modern environments. At a symposium of the Biogeography Study Group held in Oxford on January 1, methods were described for absolute dating, and for dating very recent objects. Palaeomagnetic dating and lead and caesium analysis are now becoming available to supplement pollen records and radiocarbon assays already corrected for errors detected by dendrochronological research. Again, in the field, magnetic susceptibility measurements are proving an invaluable aid in selecting representative single cores from extensive peat bogs, lake basins or peaty moorlands.

F. Oldfield (University of Lancaster) reported the preliminary but successful application of these new techniques in environments as contrasted as Sweden and New Guinea. His advocacy of the lacustrine sediments as a superior source of continuous and complete palaeochronologies is, however, open to some criticism. Such sediments may incorporate successively younger layers, duplicated or polycyclic layers, unconformities due to erosion, and homogenisation, due to alluvial and colluvial mixing, as B. Seddon (University of Reading) reported for his detailed pollen record for sediments at Llangorse lake in Powys, Wales. Clearly, differentiation between lacustrine and terrestrial sources and between riverborne and airborne pollen is necessary. It is thus desirable to examine modern pollen cycling within the adopted lake catchment and to analyse soil pollen records and pollen evidence from peats and muds.

Several papers described local palynological studies which have regional significance in Britain. It is beginning to be possible to reconstruct vegetation cover for different culture periods. Some changes, such as elm decline, are broadly synchronous (though substantial variations in timing occur at certain Welsh sites); others, such as man-made clearances between Mesolithic times and the Iron Age are more diachronous. It is becoming clear that late Mesolithic man was considerably

more advanced than archaeologists have previously believed. He partially domesticated the red deer and initiated sizeable forest clearances.

In comparing old, middle-age and young soils on Exmoor K. Crabtree (University of Bristol) and E. Maltby (University of Exeter) estimated the developmental stage reached by a soil profile by measuring the rate of accumulation of organic matter over time. By this technique again a process can be calibrated from its inception to the present day, eventually absolute soil chronologies should be available which will allow refined measurement of the ecological stability and trend of individual soil environments as related to management and planning.

The problems which recur when attempts are made to interpret archaeological evidence in environmental terms were well exposed by D. A. Davidson (University College, Lampeter) and R. L. Jones (Lancaster Polytechnic) who examined the location and distribution of Neolithic chambered cairns in the Orkneys. A model for the island of Rousay evaluated seven environmental parameters of cairns: distance from coast, nature of coast, slope, soil drainage, rockiness, altitude and visibility from the mainland of Orkney. The sites generated were compared with the actual distribution of cairns and the best approximations were found to occur for (1) nearness to a beach coastline and (2) steepness of slope. W. Kirk (Queen's University, Belfast) criticised any rationalisation of the location of cairns since they were burial places and not settlement sites. But as Frances Lynch (University College of North Wales, Bangor) has argued (in *The Effect of Man on the Landscape Highland Zone*, Council for British Archaeology Research Report II, in the press), prehistoric man may have been discriminating in the selection of both vantage points and viewpoints for burial as well as settlement. A subtle blend of the defensive and the exhibitionist, and of the imitation of natural features, may sometimes be inferred.

Lunar eclipses and Danjon's law

from David W. Hughes

LUNAR eclipses occur when the Earth's shadow is cast over the full Moon. They have an average duration of 226 min, totality (full shadow) lasting about 103 min. Sixteen lunar eclipses occurred between 1965 and 1975, the exact time of occurrence depends on the relationship between the draconic (lunar nodal) month, the synodic (identical phase) month, the precession of the nodes of

the orbit and the Earth-Moon-Sun geometry. In totality the Moon presents a fascinating spectacle—the contours of the seas and some of the craters are discernible, its hue is distinctly red and its brightness and colour vary from limb to centre creating the impression of a sphere as opposed to the flat disk of the normal full Moon.

The reddish glow is an interesting phenomenon. Rays of sunlight just grazing the edge of the Earth's globe must pass right through the thickest part of the atmosphere where they undergo refraction and are bent into the cone of shadow and fall upon the eclipsed Moon. The light also undergoes absorption due to Rayleigh scattering, the short wavelengths are attenuated much more than the long, leaving the remaining light red like sunsets on Earth. The spectrum of the light reflected from the eclipsed Moon and its variation across the disk can be explained by the absorption of light in the terrestrial ozone layer and can be used to give a concentration-height profile of ozone in the Earth's atmosphere.

In 1920 Danjon, a French astronomer, noticed a relationship between the phase of solar activity and the brightness of a lunar eclipse (*C. r. Acad. Sci. Paris*, **171**, 1127, 1920). This relationship is now known as Danjon's law and can be stated as follows: in the two years immediately after a solar activity minimum the shadow of the Earth during a lunar eclipse is very dark and has little colour. As the solar activity moves away from minimum the eclipsed Moon becomes brighter and redder until, during the seventh and eighth year after solar minimum the eclipsed Moon is at its brightest and is red, copper coloured or orange. The brightness curve then falls away very sharply to its minimum value. The maximum phase of the solar cycle passes unnoticed whereas the minimum phase is indicated by a sudden and considerable diminution in brightness and colour, this change forming a discontinuity.

To obtain this law Danjon had analysed eclipse records dating back to the time of Tycho Brahe. He subsequently used the law to estimate the times of solar minimum during the 17th, 18th, and 19th centuries, finding the general relationship that minima occurred in the years $1584.8 + 10.87n$ where n is an integer (*C. r. Acad. Sci. Paris*, **171**, 1207, 1920). Notice that the length of the solar cycle, 10.87 years as derived from lunar eclipses, is less than the currently used value of 11.2 years derived from sun spots.

Link, of the Institut d'Astrophysique, Paris, has reconsidered the underlying causes of the variations of lunar eclipse brightness described by

Danjon's Law in a recent edition of *The Moon* (**11**, 137, 1974). He finds that the phenomenon behind the law is not the absorption of the light in the terrestrial atmosphere, as originally assumed by Danjon, but some light source other than the normal refracted solar illumination. The problem is to find this source. Vassy (*J. Sci. Mét.* **8**, 1, 1958) hypothesised that the cause is a scattering layer in the Earth's upper atmosphere produced by aerosols. The spatial density of these aerosols could be affected by the corpuscular radiation flux from the Sun and the variation in density caused by the sudden change in the heliographic latitudes of the source of this radiation after solar minimum. Link examines the possible implication of this hypothesis on the twilight and daytime sky as observed from Earth. Looking at two extremes of shadow density he finds the eclipse of January 18, 1954 to be a thousand times less luminous than that of September 26, 1950. To explain the bright eclipse by aerosol scattering requires an aerosol density such that the twilight brightness would be a hundred times more than observed. The luminance of the daylight sky too is far from that needed to explain Danjon's Law.

Another source of additional light is the luminescence of lunar surface materials. This could be caused by corpuscular radiation striking the Moon during the eclipse or it could be an afterglow from the period preceding the eclipse. But recent laboratory examinations of lunar samples showed that the luminescence is much too low to explain the eclipse observations.

Two other facts must be borne in mind: first Fisher (*Smithson Misc. Coll.*, **76**, No 9, 1924) found winter eclipses to be brighter than those occurring at other seasons and second, exceptions to Danjon's Law have occurred when very dark eclipses were seen after the eruption of the volcanoes Krakatoa (1883) and Katmai, Alaska (1913).

But we must return to Link's final conclusions, that a scattering layer in the upper atmosphere, or luminescence of the lunar surface—both caused by solar corpuscular radiation—describe qualitatively the general features of Danjon's law but are quantitatively completely unsatisfactory. So the cause of the relationship remains unknown.

Erratum

In the report "G-wizardry at Dallas" by John Faulkner (**253**, 231, 1975) the scalar coupling constant was printed in the penultimate paragraph as $\gtrsim 23$ instead of $\lesssim 23$. Also Colgate's institution is New Mexico Institute of Mining and Technology, not University of New Mexico as printed.

THE central theme of the symposium was structure at the molecular level. Many fibrous proteins have a highly regular structure, for example, the collagen of tendon shows nature adopting at the molecular level the principle of successive twisting that man has developed in the rope. Man has not yet developed a molecular rope, but different methods of drawing polyethylene lead to fibres with a wide variety of mechanical properties, some with the stiffness of glass and the tensile strength of steel (Ward, Leeds). The mechanical properties may be related to the structural regularity of the molecular folds in the polymer. There is a striking similarity between the folded chains of polyethylene (Sadler, Bristol) and those of the protein in the egg stalk of the lacewing fly, *chrysopa*, but many natural polymers share with the synthetics an intermingling of regular and less regular structural regions. In the globular enzymes, the same types of chain conformation are found as in fibrous proteins, but each stretch is limited in extent so that the chain can fold to form a compact shape (North, Leeds). The recurrence of certain well defined folds in different enzymes probably indicates evolution from a common ancestral protein, though there remains the possibility that some conformations may recur just because they are energetically favourable, as do the folds in polyethylene.

The alternation of regularity with irregularity is seen too in polysaccharides, the formation of gels of which depends upon molecular chains being associated in pairs for limited distances (Rees, Unilever), interruption of the regular alternating copolymer by a sugar unit with a different conformation makes a kink in the chain, causing the molecular partnership to break and the two chains to diverge before joining up with different partners. The variety of sugar units utilised in polysaccharides permits a great range of conformations, some of which are very susceptible to changes in solvent environment (Atkins, Bristol), thus conformational changes similar to those induced in heparan sulphate by calcium may be a vital factor in cell adhesion.

In the chromatin of the cell nucleus, the nucleic acid is intimately associated with histones, basic proteins of five types. It is now beginning to appear that the histone molecules are individually globular and associate specifically to form a bead-necklace around which the nucleic acid is wound (Thomas, Cambridge).

A second theme of the conference was chemical modification of polymers. Technologists may attempt to modify a polymer in order to improve its properties, such as the drape and

Natural and synthetic polymers

With the praiseworthy intent of allowing enzymologists and polymer scientists to learn from each other, the SRC Enzyme Chemistry and Technology Committee organised a meeting on January 2 and 3 at Cambridge. In three sessions the meeting dealt with synthetic polymers, structural natural polymers and enzymes. The reports of the meeting which follow describe it from the point of view of, respectively, an enzymologist and a polymer scientist

crease-resistance of cotton fabrics (Roberts, Shirley Institute). Protein workers often use chemical modification to a different end, in probing structure and function. Very high degrees of specificity may be achieved (Dixon, Cambridge), though care must be exercised in drawing conclusions from the effects of such modifications—the activity of an enzyme may be perturbed by changes remote from its active site. Such methods have been applied elegantly in distinguishing the part played by individual subunits in a multimeric enzyme and in studying the interactions between components of a multi-enzyme complex and between the subunits of a virus (Perham, Cambridge).

The Cambridge meeting established interesting overlaps between the work on natural and synthetic fibres, for example in the molecular basis of mechanical properties and in the thermodynamic and kinetic constraints on the folding pathways. While the programme had a bias towards the natural fibres, showing clearly the great subtlety, elegance and efficiency with which nature has evolved a wide variety of functions from a limited repertoire of structural elements, it is clear that man has already achieved enormous progress in a very short time in making an almost comparable variety of synthetic materials.

Experiments with model compounds (Kirby, Cambridge) show how chemical reaction rates depend critically upon the reacting groups being constrained into an appropriate geometry, such studies are vital to the eagerly awaited development of catalysts with the efficiency and specificity of enzymes—which will doubtless owe much to comparative studies of natural and synthetic polymers.

A C T NORTH

SCIENTISTS have great trouble even in communicating the meaning of their work to each other. This was probably the main conclusion to be drawn from the symposium which, because of the lack of dialogue or (apparently) of flashes of inspiration, must be judged a failure. The reasons may be that the speakers did not address themselves sufficiently to areas of potential overlap, that the discussion was too limited or that the two subjects are irrelevant to each other.

Polymer science groups in the USA are increasingly turning their interest to biological macromolecules, spurred on by the increase in the fortunes of the NIH compared to those of the Defense Department a few years ago. This has resulted in work on solid state and solution properties of polysaccharides and polypeptides, one obvious avenue, and in the study of collagen ultrastructure and its relationship to mechanical properties presented by R G C Arridge and L Gathercole of Bristol and carried out jointly with Case Western Reserve University.

One thing that did emerge was the relative lack of understanding of physical aspects of enzyme structure such as the denaturation and renaturation processes, the nature of subunit interactions, and of questions such as "How large must a protein be to have a hydrophobic core?" posed by T L Blundell during the discussion. This was reinforced by the parallel between J O Thomas's review of work on chromatin structure at Cambridge and D M Sadler's of polymer crystallisation and morphology. Both topics are almost baroque in their complexity, the methods used are completely different, yet the problems are very much related. It is to be hoped that researchers starting from the synthetic polymer direction can contribute to these subjects, though the immediate problem for a person used to working with kilograms of sample is to learn techniques for handling natural polymers, and here cooperation between the groups is essential.

The two geological time scales

by W. B. Harland

Sedgwick Museum, Downing Street, Cambridge CB2 3EQ, UK

Several international bodies are currently preoccupied with the task of establishing, defining and standardising time scales for geology. Geological ages may be expressed on either of two alternative scales often distinguished somewhat misleadingly as 'relative' and 'absolute' ages

THE chronostratigraphic scale (with its hierarchy of eon, era, period, epoch, age, and chron) has developed slowly over more than 150 years. Its divisions were initially unconformities, conceived of as natural chapters in Earth history, but these were later superseded by divisions defined palaeontologically. The scale is currently being redefined on a global basis, with boundaries standardised at reference points in type sections, in order to produce a Standard Stratigraphic Scale¹ or Standard Global Chronostratigraphic (Geochronologic) Scale². The principle has been illustrated by the establishment of one point on the scale—the Silurian–Devonian boundary³.

The geochronometric scale⁴, unlike the chronostratigraphic scale is based on a unit of duration, originally defined as the geochrone⁵, but since the development of radiometric methods the terrestrial year has been the only unit in general use. The geochronometric scale is periodic, that is, simply the numerical multiplication in steps of 1,000 of the agreed unit ($10^0\text{yr} = 1\text{a}$, $10^3\text{yr} = 1\text{ka}$, $10^6\text{yr} = 1\text{Ma}$, $10^9\text{yr} = 1\text{Ga}$). This scale is already in use whenever an age is expressed in years. The geological year is not yet standardised as it is necessary to choose between the Ephemeris 1900 year of the International Union of Astronomers 1957, and the year based on the caesium second of the International Conference of Weights and Measures 1957, but that is of theoretical interest only¹. Of practical interest, however, is the often expressed wish to divide the whole scale into longer spans of time with internationally agreed names.

The terminology used for the two scales is in some doubt for many years the term 'geochronology' has been used mainly within the context of the geochronometric scale (for example, IUGS Subcommittee of Geochronology), whereas the IUGS Subcommittee of Stratigraphic Classification (following the American Stratigraphic Code) has used the same term when referring to time spans of the chronostratigraphic scale². To avoid confusion the term 'geochronometric' can be used unambiguously for a scale based on years as the term 'geochronology' might become used generally with both scales.

Both are framework scales⁶, they both express time but in quite different ways. They are both artificial, they cannot be discovered but only decided by convention (for example, 'golden spikes' for the chronostratigraphic scale, and a standard second for the geochronometric scale). The framework allows the expression of the ages of phenomena in a common language and the phenomena (biological evolution, magnetic reversals, climatic fluctuations, tectonic events, nuclear decay, and so on) are necessary for correlation and the 'determination' of age. It is an historical consequence and not a scientific necessity that previously has led biostratigraphy to be concerned largely

with the development of the chronostratigraphic scale whereas with isotope geology the geochronometric scale has been more important. Whereas all methods may be useful in connection with either scale, each of which has its distinctive advantages, metazoan fossils and precise biostratigraphy are limited to the last seventh of Earth history and that has resulted in the almost exclusive use of the chronostratigraphic scale by Phanerozoic geologists whereas Precambrian geologists use mainly the geochronometric scale.

I suggest that this is neither a necessary nor a useful restriction and that more active steps should be taken to extend the use and range of each scale independently. Until that is done we are liable to use a hybrid scale^{7,8}—Precambrian geochronometric and Phanerozoic chronostratigraphic—the latest Precambrian division being a hybrid with its beginning defined in years (whatever that means in terms of geological history) and its end defined in an initial Cambrian stratotype (whatever its age in years). This hybrid needs rooting out along with the many other "weeds in the Precambrian rock garden"⁹. It inhibits the proper development and use of each scale if each, instead of coexisting with the other, serves only one part of a single scale⁸. In parallel they supplement each other and invite mutual calibration¹⁰.

Extension of the chronostratigraphic scale

For some time the methods so successful in Phanerozoic stratigraphy have been applied to Precambrian rocks, and

	? Early		

* Informal names and divisions of Precambrian time as proposed by IUGS Precambrian Subcommittee and borrowed here to show that the divisions should correspond to named divisions of the geochronometric scale. But the boundaries of these divisions have yet to be decided, and may not correspond to the values suggested here, in which case this scheme might be modified accordingly.

Precambrian divisions along these lines have been proposed¹¹⁻¹⁴. Indeed, the time is ripe, in connection with the standardisation of the initial Cambrian boundary¹⁵, similarly to define some earlier divisions¹⁶. These should not be defined in terms of general events (such as the occurrence of plant life or glaciation), even though that may provide hope of good correlation. Table 1 indicates how it could be achieved. It would be necessary to decide on a classification, a nomenclature and a standardisation (at reference points in selected boundary stratotypes). Table 1 illustrates these points.

New classification and nomenclature of the geochronometric scale

At the same time there is pressure from workers concerned with Precambrian geology to improve the geochronometric scale by defining named divisions longer than a million years. Here, again, it is necessary to decide on a classification, a nomenclature and a standardisation.

The example shown in Table 2, like that shown in Table 1 is designed rather to illustrate the general principle than to press its particular merits, so that out of criticism an agreed scale may emerge.

An hierarchy with divisions larger than a year would be useful as many events have ages which would be easier to express in divisions of a longer duration. I suggest two divisions. The larger are compounded of smaller divisions of 0.5 Ga ($= 0.5 \times 10^9$ yr). I considered a scheme with divisions at -1.0, -2.0, -3.0, -4.0 Ga (that is, a gignennial system) but rejected it because it might have put into words a reversed system as confusing as centuries BC. I then tried a scheme with four names for spans of up to 1.5 Ga and a threefold subdivision of each—early, middle and late (or with subscripts 1, 2 and 3, as in Russian stratigraphic abbreviations).

I chose the division at -2.5 Ga because it is probably the

most popular point for dividing Precambrian time⁹. The 1.5 Ga division may be termed an *aevum* (eon) and the 0.5 Ga span an *aetas* (age).

Existing nomenclature is Precambrian-orientated, loaded with associations, and ambiguous or hybrid, so new terms are needed for the new task. They will need to be clear and convenient if they are to be used in preference to the obvious numerical alternative.

Most stratigraphic roots are derived from the Greek (chron, period, era, eon, eo, proto, archaeo, palaeo, meso, neo and kaino) possibly because they combine more elegantly than Latin roots. Latin has hardly been used so far, so I suggest that Greek be used with the chronostratigraphic scale and Latin be used with the geochronometric scale (with the exception of 'geochronometry'). I considered several Latin roots: *ortus* and *natus* (born), *origo* (origin), *priscus* (ancient), *matutinus* (early), *vetustus* and *antiquus* (old), *medius* (middle), *serus* (late) and *novus* (new). Words like *novus* may be combined in the substantival form *novum tempus* (novotime) and the adjectival form *novotemporalis* (novotemporal).

I suggest that for general international use the abbreviated form novotemp (or novot) be used. Many scientists casually use adjectives as nouns: thus, 'The Precambrian' is a common abbreviation for the Precambrian rocks, history, time, research, or whatever noun is appropriate in context. So in this way the single adjectival abbreviated form might serve as an international technical name without inflection.

The particular names suggested here are not necessary to the scheme and others may be devised. Greek roots are easier and if used with a distinctive suffix may be more acceptable if defined and agreed as a whole.

Standardisation will be simply in years and there is a consensus that very round figures be used so as to avoid any implication of definition by historical events.

Each subdivision (*aetas*) is defined as a precise periodic multiple of 500 Ma. Strictly, years BP go back from a datum at 1950 but it is suggested that, unless a subdivision Latest Novotime beginning at 1950 be used, Late Novotime be extended. Similarly, at the beginning of Priscotime a different procedure may be considered.

The numerical expression of the scale could be distinguished by the negative sign from the same value used as a duration, in preference to the use of BP (see ref. 17).

The magnitude of time span of the proposed divisions is suitable for general discussion of the physical and chemical evolution of the Earth and indeed of the Solar System, so providing a convenient planetary descriptive scale. Cosmologists may advise on how to define the early spans of Priscotime if it be desired to consign the early history of the Earth mostly to its third subdivision.

Scales independent of history

These suggestions distinguish clearly between the chronostratigraphic and geochronometric scales and also avoid the restriction of the latter to Precambrian time ('Precambrian' belongs to the former). Nevertheless, the geochronometric scale will serve Precambrian time with eight of its nine or ten subdivisions. If a hybrid division be required it can be expressed in hybrid form, namely, Precambrian Novotemp (or PC Novot).

It is desirable to avoid names for the geochronometric scale that are associated with the confused history of Precambrian stratigraphy. There are, however, a few rather strong weeds in Rankama's 'rock garden' that will be difficult to eradicate, namely Archaeozoic, Proterozoic, and Eo-Cambrian. These may usefully continue without definition. There is an advantage in retaining a generally understood nomenclature which is intentionally vague so that when an uncertain age is expressed the old names can be used. The new scales would thereby be spared misuse.

In the meantime, if Early, Middle and Late Precambrian time be used as informal names (as suggested by Rankama through the Precambrian Subcommittee) the values chosen

for calibration should also be used for dividing Antiquot, Mediot, and Novot

Finally, agreement on the two artificial scales suggested merely improves the equipment for dealing with the real problems of geology requiring the use of all kinds of phenomena for correlation, and describing their evolution on either scale. Phenomena also need some regulation as to their terminology and nomenclature but their history can never be regulated, and this is the fundamental distinction between the framework and phenomenon categories⁶. Both scales are needed to investigate geological history and to do so they should avoid dependence on it.

Professor C O Brink contributed the classical expertise in proposing the new Latin terminology

Ethidium bromide inhibits appearance of closed circular viral DNA and integration of virus-specific DNA in duck cells infected by avian sarcoma virus

Ramareddy V. Guntaka, Brian W. J. Mahy*, J. Michael Bishop & Harold E. Varmus

Department of Microbiology University of California, San Francisco, California 94143

The DNA of avian sarcoma virus assumes a closed circular configuration before integration into the host cell chromosomal DNA. Ethidium bromide reduces the formation of superhelical viral DNA and concurrently blocks integration of the viral genome. Inhibition of integration of viral DNA results in the inhibition of virus replication.

FOLLOWING infection of permissive cells by RNA tumour viruses, a DNA intermediate is transcribed from viral RNA (ref. 1) and subsequently integrated into the host cell genome². Although synthesis of viral DNA seems to be crucial in the virus life cycle, it has not been established whether virus production depends on integration of viral DNA. Since no viral mutants defective in integration have been isolated, alternative approaches have been sought to document the necessity of integration for virus replication. One such approach is to block integration with chemical inhibitors. We show here that ethidium bromide (EB), a phenanthridine dye, allows synthesis of normal quantities of viral DNA but blocks its integration into the host DNA, probably by interfering with the formation of covalently closed circular DNA. This closed circular molecule, which can be demonstrated in alkaline sucrose and equilibrium density gradients, is presumably the form of viral DNA just before its integration. We also present evidence for a direct relationship between the amount of viral DNA integrated and the amount of virus-specific RNA produced by the infected cell.

EB affects viral DNA integration

Peking duck cells were pretreated for 6 h with EB (1.0 $\mu\text{g ml}^{-1}$) and then infected with B77 avian sarcoma virus in the presence of the inhibitor. Forty hours after infection, DNA was isolated from untreated (control) and EB-treated cells and assayed for virus-specific nucleotide sequences by testing its capacity to influence the reassociation of double-stranded viral DNA synthesised *in vitro*³. In the experiment presented in Fig 1a

Fig 1 Effect of EB on integration of viral DNA. Peking duck cells (prepared from 12–14-d-old embryonated eggs) were grown to a density of $4\text{--}5 \times 10^6$ per 100 mm plate. Half of the cells were infected with B77 virus at a multiplicity of infection of 3 in the presence of polybrene ($2 \mu\text{g ml}^{-1}$) and the other half was pretreated for 8 h with EB ($1.0 \mu\text{g ml}^{-1}$) and then infected in the presence of the inhibitor. After 40 h incubation, high molecular weight DNA was extracted and tested for integration as described by Varmus *et al*³. To detect the presence of virus-specific nucleotide sequences, radioactive duplex virus-specific DNA (representing about 30% of the total viral genome²) was denatured and reassociated in the presence of various samples of cellular DNA. Acceleration of the reassociation of the radioactive DNA indicates the presence of virus-specific nucleotide sequences in the cellular DNAs. Each reaction mixture contained radioactive DNA (1.6 ng ml^{-1} , $15,000 \text{ cpm ng}^{-1}$). Reassociation was monitored by fractionation on hydroxyapatite. *a*, (○) normal duck DNA (1.6 mg ml^{-1}), DNA (Δ) from B77-infected control (1.6 mg ml^{-1}) or (▲) EB-treated (1.5 mg ml^{-1}) duck cells. *b*, (○) normal duck DNA (1.6 mg ml^{-1}), (□) network DNA (1.3 mg ml^{-1}) or (■) supernatant DNA (1.1 mg ml^{-1}) from control cells or (Δ) network DNA (1.3 mg ml^{-1}) or (▲) supernatant DNA (0.5 mg ml^{-1}) from EB-treated cells.

Table 1 Inhibition of integration by EB

Sample	Total DNA		Network DNA		Supernatant DNA	
	$C_{0t_{1/2}}$	copies per cell	$C_{0t_{1/2}}$	copies per cell	$C_{0t_{1/2}}$	copies per cell
Uninfected	1.0×10^{-2}	0.00	9.2×10^{-3}	0.00	9.2×10^{-3}	0.00
Infected untreated	1.7×10^{-3}	1.20	2.0×10^{-3}	1.10	3.7×10^{-3}	0.60
EB-treated	1.7×10^{-3}	1.20	7.0×10^{-3}	0.15	2.0×10^{-3}	2.80

$C_{0t_{1/2}}$ values were obtained from reassociation kinetics given in Fig. 1. Copy numbers were computed from $C_{0t_{1/2}}$ as described by Gell et al.¹⁷

and Table 1, 1.2 copies per cell of viral DNA were synthesised in either the presence or absence of EB, indicating that EB has no effect on the net synthesis of viral DNA. In some experiments (data not shown), 15–20% inhibition was observed with this dose of EB. Since virtually normal levels of viral DNA are synthesised, these data indicate that, in contrast to the results of studies *in vitro*⁴, EB does not inhibit the action of reverse transcriptase in the infected cell.

Fig. 2 Duck cells, either untreated or pretreated for 8 h with EB, were infected with B77 virus at a multiplicity of infection of 5 in the absence or presence of the inhibitor. After 38 h, high molecular weight DNA was isolated and assayed for integration as in Fig. 1. Also, one plate from each batch was labelled with ^3H -uridine ($16 \mu\text{Ci ml}^{-1}$, 27 Ci mmol^{-1}), and fluids were collected and banded in equilibrium sucrose gradients as described in the legend to Table 1. One plate from duck cells infected 7 d previously was labelled similarly after 24 h (\square) or 48 h (\blacksquare) treatment with EB. \circ , Integration of viral DNA, \blacktriangle , virus production.

Integration of viral DNA into the cell genome was, however, affected by EB. The DNA was tested for integration by a recently described technique². Under appropriate conditions, reassociated cell DNA reassociates to form network-like structures, viral DNA covalently linked to strands of cell DNA appears in these structures. Network DNA from cells infected in the absence of EB accelerated the rate of reassociation of

labelled viral DNA by a factor of 5, whereas the network DNA from EB-treated cells had only a marginal influence on the reassociation (Fig. 1b). The data indicate that less than 15% of viral DNA (0.15 copy compared with 1.1 copies in the control) was integrated in the presence of EB (Table 1). As expected, DNA from EB-treated cells that had not entered into networks markedly decreased the $C_{0t_{1/2}}$ of labelled viral DNA, indicating considerable (six- to eightfold) enrichment of virus-specific sequences in the supernatant which included all unintegrated viral DNA. From these results we conclude that EB does not inhibit viral DNA synthesis, but prevents integration of viral DNA into host cell DNA.

Similar results were obtained with EB ($0.5 \mu\text{g ml}^{-1}$) but with still lower concentrations, the extent of inhibition decreased significantly (Fig. 2). Concentrations of EB above $1.0 \mu\text{g ml}^{-1}$ not only blocked integration but also suppressed synthesis of viral DNA. For example, in the presence of EB at $2.0 \mu\text{g ml}^{-1}$ only 45% of control levels of viral DNA was synthesised, and integration was totally inhibited. The suppression of viral DNA synthesis by the higher doses of EB could be caused by cytotoxic effects of the drug. Doses of $1.0 \mu\text{g ml}^{-1}$ or less had little or no effect on cell growth during a 48-h exposure (see below, Table 2), whereas higher doses severely depress cell growth (R. V. G., B. W. J. M., J. M. B., and H. E. V., unpublished).

EB and supercoiled viral DNA

Recently, we have shown that at least 10–20% of viral DNA exists in a covalently closed duplex circular form 8–10 h after infection of duck cells by avian sarcoma virus^{5,6}. Since EB binds to duplex DNA and causes unwinding of the molecule, we proposed that EB might intercalate with double-stranded viral DNA to prevent or reverse the formation of supercoiled DNA (form I) and thereby inhibit integration. The following evidence supports this notion.

Integration of viral DNA into the cell genome starts about 10 h after infection². If formation of supercoiled viral DNA is required for integration, we expect maximum levels of this species before integration. Therefore, untreated and EB-treated duck embryo fibroblasts were infected for 9 h in the absence and presence of the dye and cells were fractionated according to the procedure described by Hirt, which has been used to separate papovavirus DNA from host cell DNA⁷. The DNA in the Hirt supernatant was analysed for the presence of closed circles in an alkaline sucrose gradient. Three distinct peaks of viral DNA, detected by hybridisation to cDNA (DNA complementary to viral genome), were observed in both control and EB-treated supernatant fractions. About 18% of the

Table 2 Effect of EB on virus production in B77-infected duck cells

	Cells per 100-mm plate	Viral DNA copies per cell	Integration (%)	^3H -uridine incorporation (c.p.m.)	FFU ml ⁻¹
Control	8.7×10^6	1.7	100	3,095	7.5×10^4
EB	7.2×10^6	1.5	17	417	8.5×10^3

Duck cells (4×10^6 per 100 mm plate), untreated or pretreated for 4 h with EB ($1.0 \mu\text{g ml}^{-1}$) were infected with B77 virus at a multiplicity of infection of 5 for 40 h in the absence or presence of EB. High molecular weight DNA was isolated and assayed for integration as described in the legend to Fig. 1. One plate from each group was labelled with ^3H -uridine ($8 \mu\text{Ci ml}^{-1}$, 27 Ci mmol^{-1}) for 8 h and the growth fluids were banded in an equilibrium sucrose gradient (15–55% sucrose in 0.1 M NaCl, 10 mM Tris-HCl, pH 7.4, 10 mM EDTA, SW41 rotor, 3.5 h at $40,000 \text{ rpm}$ and 4°C). The tritium label banding at a density of $1.15\text{--}1.17 \text{ g ml}^{-1}$ was taken as the amount incorporated into the virion RNA. Aliquots of growth fluids from control and EB-treated samples were also assayed for virus production by focus formation on chicken cells. FFU, Focus-forming units.

Fig 3 Sedimentation of viral DNA in alkaline sucrose gradient. Duck cells, either untreated or pretreated with EB ($0.25 \mu\text{g ml}^{-1}$) for 14 h, were infected with B77 virus at a multiplicity of infection of 4–5 in the absence or presence of EB ($1.0 \mu\text{g ml}^{-1}$). After 9 h, cells were collected and fractionated as described by Hirt⁷. DNA was isolated from the Hirt supernatant by treatment with pronase followed by phenol extraction. After ethanol precipitation, the DNA was treated with pancreatic RNase in 10 mM Tris-HCl (pH 7.4)–10 mM EDTA, re-extracted with phenol, ethanol precipitated and analysed on a 5–20% sucrose gradient in 0.3 M NaOH, 0.7 M NaCl and 1 mM EDTA. Centrifugation was for 3 h in a SW41 rotor at 40,000 r.p.m. and 20°C . Fractions were collected from the bottom of the gradient, supplemented with calf thymus DNA ($50 \mu\text{g ml}^{-1}$) to serve as carrier, and then heated for 2 h at 80°C to reduce the size of DNA. The fractions were neutralised and precipitated with ethyl alcohol. DNA was collected by centrifugation and assayed for virus-specific sequences using ^3H -labelled cDNA ($1,270 \text{ c.p.m. per fraction}$, $20,000 \text{ c.p.m. ng}^{-1}$). Annealing was for 4 d at 68°C in 0.6 M NaCl in 40 μl volume. Resistance of ^3H -cDNA to S1 nuclease was determined as described previously¹⁸. Under these conditions of annealing, the reaction was linear from 0.05 to 0.5 ng ($5\text{--}30\%$ S1 resistance) of viral DNA¹⁶. This permits quantitation of virus specific DNA in an individual sample. Supercoiled SV40 (form I, 53S) and single-stranded circular fd DNA (20S) were run in parallel gradients. Sedimentation is from right to left. \circ , Control, \triangle , EB

virus-specific DNA sedimented at 62–65S (peak I, Fig 3), this species represents supercoiled viral DNA^{5,6} (R V G *et al*, unpublished). More than 60% of the viral DNA is much smaller in size (molecular weight $< 1.0 \times 10^6$, peak III). About 10–15% sedimented at approximately 22S, corresponding to a molecular weight of 3×10^6 to 3.5×10^6 (equivalent to the size of the 35S subunits of the viral genome¹). EB suppressed the formation of closed circles (peak I) by a factor of 4–5, without affecting the other forms (peaks II and III, Fig 3), less than 0.1 ng out of 2.8 ng was found as supercoiled DNA in the EB-treated sample compared with 0.5 ng out of 2.4 ng in the control (see legend to Fig 3). These results suggest that EB specifically blocks or reverses the formation of supercoils. Further evidence in support of this comes from the following experiment.

Supercoiled DNA (form I) binds less EB than open circular (form II) or linear (form III) duplex DNA⁸. Consequently, form I DNA bands at a higher buoyant density (about 0.035 g ml^{-1} greater than forms II and III) in CsCl-EB equilibrium density gradients⁸. Analysis of the Hirt supernatant fraction from duck cells infected for 9 h with B77 virus revealed that two separate peaks of viral DNA could be resolved with a density difference of about 0.036 g ml^{-1} , under similar conditions

SV40 forms I and II were, as expected, separated by a density difference of 0.038 g ml^{-1} . The hybridised viral DNA banding at higher density is consistent with a closed circular molecule.

In agreement with the results shown in Fig 3, EB suppressed the formation of only the supercoiled DNA by more than 80% (Fig 4). Computation of the amount of viral DNA from percentage hybridisation¹⁶ indicates that comparable amounts of viral DNA were synthesised in EB-treated and untreated cells (about 6 ng), but less than 0.2 ng of the total banding as form I in the EB-treated sample as opposed to about 1.3 ng in the control.

To demonstrate unequivocally that the DNA binding at the higher density in Fig 4 is closed circular DNA, we showed that its density in CsCl-EB gradients could be altered by limited exposure to pancreatic DNase. Viral DNA from the Hirt supernatant of cells infected for 9 h was centrifuged to equilibrium in a CsCl-EB gradient, 15–20% of the total viral DNA cosedimented with PML21 form I (Fig 5a). When single-strand breaks were introduced by pancreatic DNase, both the

Fig 4 Equilibrium gradient centrifugation of viral DNA. The remaining portions of the Hirt supernatants from duck cells infected with B77 virus in the presence or absence of EB (see legend to Fig 3) were analysed in a CsCl-EB gradient. To a 6-ml sample in 10 mM Tris-HCl–3 mM EDTA 6 g, CsCl and EB ($300 \mu\text{g ml}^{-1}$) were added and centrifuged for 66 h in a type 40 rotor at 33,000 r.p.m. and 20°C . ^3H -labelled SV40 DNA was also centrifuged in a parallel gradient. Fractions were collected and assayed for virus-specific DNA with ^3H -cDNA ($1,330 \text{ c.p.m.}$, $20,000 \text{ c.p.m. ng}^{-1}$) as described in Fig 3. The viral DNAs corresponding to supercoiled and open or linear forms banded at 1.594 and 1.558 g ml^{-1} respectively. SV40 form I has a buoyant density of 1.590 g ml^{-1} under similar conditions and banded between fractions 8 and 14. \circ , Control, \triangle , EB

viral DNA and PML21 marker DNA shifted to a lighter density peak (Fig 5c), corresponding to form II or III. Re-banding of the same material without DNase treatment showed that form I DNA was still intact (Fig 5b). This effect of pancreatic DNase on the density shift of viral DNA strongly supports our conclusion that at least a portion of the viral DNA synthesised *in vivo* exists as a closed circular molecule.

We have consistently observed that a measurable amount of viral DNA bands at a position intermediate to the heavy and light density peaks of DNA, thereby broadening the bandwidth of form I DNA (Figs 4 and 5). The density pattern of this DNA is unchanged by treatment with pancreatic DNase. The nature of this species is at present unclear and is being investigated.

Fig. 5 Conversion of form I DNA to form II by pancreatic DNase. Duck cells were infected with B77 virus at a multiplicity of infection of 6 and after 9 h, cells were collected and fractionated as described by Hirt⁷. DNA was isolated from the Hirt supernatant as described in the legend to Fig. 3. ³H-labelled PML21 plasmid DNA (molecular weight 7.1×10^6 dalton) was added to the supernatant DNA and banded in an equilibrium CsCl-EB gradient (6.3 g CsCl in 6.8 ml sample containing EB at $300 \mu\text{g ml}^{-1}$). a, One-fourth volume from alternate fractions was hybridised to ³²P-labelled cDNA as in Fig. 3. The DNA banding at heavy density (fractions 4-12) was pooled and EB was removed by passing through Dowex-AG50. Calf thymus

DNA ($60 \mu\text{g}$) was added and the pooled sample was dialysed against 20 mM Tris-HCl to remove CsCl. The sample was divided into two equal portions, one portion served as control (b) and the other half was treated with pancreatic DNase (c) (Worthington) in 10 mM MgCl₂, 20 mM Tris-HCl, pH 7.4, 10 mM NaCl, bovine serum albumin ($30 \mu\text{g ml}^{-1}$) and $5 \times 10^{-5} \mu\text{g}$ DNase for 20 min at room temperature. The reaction was stopped by the addition of 50 mM EDTA and the samples were centrifuged to equilibrium in CsCl containing EB ($300 \mu\text{g ml}^{-1}$). The conditions of centrifugation and hybridisation were as described in Fig. 4. O, Percentage hybridisation to ³²P-cDNA, Δ , ³H-labelled PML21.

EB inhibits virus production

To explore the relationship between integration of viral DNA and virus production, the following experiments were performed. Cells were pretreated with $1.0 \mu\text{g ml}^{-1}$ EB for 6 h and infected for 40 h in its presence. DNA was then isolated and tested for the presence and integration of virus-specific nucleotide sequences. Virus production was monitored by the incorporation of ³H-uridine into the RNA of mature virus released into the medium and by assay of the culture medium for focus-forming activity. In addition, the rate of synthesis and concentration of virus-specific RNA in the infected cells were measured by hybridisation of cellular RNA to virus-specific complementary DNA (cDNA) synthesised *in vitro*⁹. The results from a typical experiment (Table 2) show that EB ($1.0 \mu\text{g ml}^{-1}$) suppressed integration and virus production coordinately by a factor of 6-8. Measurement of virus-specific RNA in the EB-treated cells by hybridisation to ³H-labelled cDNA gave similar results (Table 3). EB at $1 \mu\text{g ml}^{-1}$ reduced the concentration of viral RNA by about 80% as early as 24 h after infection, and the degree of inhibition did not change appreciably during 72 h. Substantial amounts of input viral RNA, however, result in high levels of background and thus might obscure the total effect of EB on viral DNA synthesis in this type of experiment. This problem can be overcome by studying the effect of EB on the *de novo* synthesis of virus-specific RNA. Therefore, 48 h after infection, cells were pulse-labelled with ³H-uridine, and RNA was isolated and analysed for virus-specific sequences by hybridisation to

unlabelled cDNA as described previously¹⁰. In these conditions EB inhibited synthesis of virus-specific RNA by approximately 75% (Table 4), the reduction being proportional to the reduction in the amount of viral DNA integrated into cell DNA.

The data in Fig. 2 further substantiate the conclusion that virus production depends on integration of viral DNA. There is a good correlation between the extent of viral DNA integrated and the magnitude of virus production. The inhibition of viral replication is not a simple consequence of the effect of EB on cell growth for there was only a barely perceptible decrease in the number of cells (Table 2). Moreover, the effect of EB on virus production is appreciable only if the inhibitor is added before integration. Addition of the dye ($1.0 \mu\text{g ml}^{-1}$) to cells after 24 h of infection (data not shown) or to fully infected cells producing virus (Fig. 2) did not inhibit virus production. These results strongly suggest that integration of viral DNA into the cell genome is mandatory for virus production.

Our results are different from those obtained by Reichert and Hare¹¹, who demonstrated that virus replication is unaffected by EB at $1.0 \mu\text{g ml}^{-1}$. Substantial differences in the experimental protocols used might partly explain this dissimilarity. Bader¹², on the other hand, found that this concentration of EB reduced viral RNA synthesis by 60% either in JSL-V5 cells infected by the Rauscher strain of murine leukaemia virus or in chick embryo fibroblasts infected by Rous sarcoma virus. We observed similar inhibition of virus production in chick cells (70%) as opposed to duck cells (80-85%) in the presence of EB ($1.0 \mu\text{g ml}^{-1}$).

Table 3 Synthesis of B77 viral RNA as analysed by hybridisation to cDNA

Time after infection (h)	Integration (%)		$C_{t_{1/2}}$ (mol s ⁻¹)		Virus-specific RNA (%)		Inhibition (%)
	Control	EB	Control	EB	Control	EB	
24	—	—	5.5×10^2	2.5×10^3	0.004	0.0008	78
48	100	15	2.4×10^2	1.3×10^3	0.009	0.0015	84
72	—	—	1.1×10^2	6.0×10^2	0.020	0.0030	82

Duck cells were pretreated with EB ($1.0 \mu\text{g ml}^{-1}$) for 2 h and infected with B77 virus in the presence of the inhibitor. Control cells did not receive EB. At the indicated times, cells were collected and RNA was extracted with SDS-pronase-phenol¹⁸. The RNA was then hybridised to ³H-labelled cDNA synthesised *in vitro*. Details of this technique were published elsewhere¹⁸. DNA was tested for integration as described in the legend to Fig. 1. The amount of virus-specific sequences in the total cell RNA was calculated from the $C_{t_{1/2}}$ (2×10^{-2}) obtained with purified 70S virion RNA and cDNA¹⁸. Avian sarcoma virus-transformed cell RNA has a $C_{t_{1/2}}$ ranging from 2 to 10 suggesting that 0.2-1% of the total RNA is virus-specific.

Table 4 Effect of EB on virus-specific RNA

Sample	Hybridisation input		Radioactivity in hybrid (%) [†]		Virus-specific RNA (%) [§]
	³ H*	³² P†	³ H	³² P	
Control	470,655	1042	0.28	61.0	0.46
EB-treated	373,291	1169	0.08	65.0	0.12

*Duck embryo cell monolayers were pulse-labelled for 100 min with ³H-uridine (1 mCi ml⁻¹ in nucleoside-free medium) 48 h after infection with B77 virus in the presence or absence of EB (1.0 µg ml⁻¹). At the conclusion of the pulse, total cell RNA was extracted as described previously¹⁸. The specific activity of the purified RNA was 1.0 × 10⁶ c.p.m. µg⁻¹.

†³²P-labelled 70S RNA (specific activity 1 × 10⁶ c.p.m. µg⁻¹) was purified from B77 virus⁹.

‡The hybridisation mixture in a total volume of 10 µl 2 × SSC (NaCl (0.15M)—Na citrate (0.015M)) contained the indicated amounts of ³H-cell RNA and ³²P-70S B77 RNA plus 24 µg yeast RNA and either 30 ng unlabelled cDNA synthesised using Prague-C Rous sarcoma virus or 30 ng phage λ DNA as control. After annealing for 24 h at 68°C, the percentage of RNA present in RNA-DNA hybrids was determined essentially as described by Parsons *et al.*¹⁰ Results were corrected for a background of 0.3% in control samples.

§Calculated as ³H hybridised (%) / ³²P hybridised (%) × 100.

The claims that virus production occurs in mitochondria^{13,14} have been challenged¹². Since EB selectivity inhibits mitochondrial RNA transcription and DNA replication¹⁵, our results could be interpreted to mean that virus production occurs in mitochondria, or that a function involved in mitochondrial DNA replication also participates in viral DNA replication and integration. This seems unlikely, however, for two reasons: (1) although viral DNA synthesis occurs in the cytoplasm shortly after infection, virus-specific DNA subsequently migrates into the nucleus and integrates with chromosomal DNA¹⁸, and (2) mitochondrial DNA, isolated from B77-transformed duck cells, did not hybridise to virus-specific ³H-labelled cDNA (R.V.G. unpublished). These results argue against the possibility that mitochondria are involved in virus replication and support Bader's results¹².

Molecular events before viral DNA integration

We have presented evidence favouring the following scheme for the synthesis of viral DNA after infection by avian sarcoma viruses. Viral DNA is made in the cytoplasm during the first 6 h after infection as a linear (or open circular) duplex molecule of a length similar to that of a subunit of the viral RNA genome (molecular weight 3.0 × 10⁶)^{5,6,16}, these molecules are unusual in that the predominant form contains full length strands complementary to the viral genome ('minus' strand) but relatively short 'plus' strands of DNA²⁰ (less than 1.0 × 10⁶ daltons, H.E.V. *et al.*, in preparation). Viral DNA then migrates into the nucleus at about the time that we have observed the supercoiled form of viral DNA¹⁶. Under ordinary circumstances, all or a substantial portion of viral DNA becomes integrated into the cell genome between 9 and 24 h after infection². The

presence of EB suppresses the accumulation of closed circular viral DNA, presumably by intercalation into DNA duplexes. Since the accumulation of closed circles and the integration of viral DNA are reduced concomitantly and to similar extents, we propose that a circular molecule is the form which undergoes the crossing-over step(s) required for integration. If our hypothesis is correct, the mechanism of integration for RNA tumour viruses is fundamentally similar to that for several DNA tumour viruses¹⁹. The molecular mechanism by which circles are formed remains uncertain.

Since viral RNA and progeny virus are not made when integration of viral DNA is blocked by EB, it seems that integration is a mandatory step for full expression of the viral genome. We cannot as yet exclude the possibility that the drug also exerted subtle effects on cell metabolism unrelated to viral events.

We thank L. Fanshier, J. Jackson and S. Heasley for assistance. This work was supported by grants from the American Cancer Society and the US Public Health Service and a contract within the Virus Cancer Programme of the National Cancer Institute. R.V.G. acknowledges a Senior Dernham Fellowship of the American Cancer Society, California Division. H.E.V. is a recipient of a research career development award from the National Cancer Institute. B.W.J.M. was supported by an Eleanor Roosevelt Fellowship from the International Union against cancer.

Note added in proof Closed circular viral DNA has also been identified in mouse cells infected by murine leukaemia virus (Gianni, A.M., Smotkin, D., and Weinberg, R.A., *Proc natn Acad Sci*, (in the press)).

letters to nature

On the planetary theory of sunspots

It has been proposed^{1,2} that sunspot activity is affected by positions of the planets, and calculations have been presented³, which purport to show that planetary tides on the Sun vary in the same way as the sunspot variations. We believe that the apparent agreement of the sunspot cycle with planetary tidal effects is an artefact of the calculation.

The calculation in question³ was used to compute the absolute value of the difference in tidal potential between Earth-Venus

conjunctions and oppositions at the sub-Jupiter solar point. The effect of Mercury, one of the strongest tide-raising planets was ignored on the basis that its period is short compared with that of sunspot activity. The absolute value of the tide and the effect of partial line-ups of Venus (or the Earth) with Jupiter were not computed. Furthermore, it is not clear that the absolute difference between opposition and conjunction tidal potentials has any physical meaning.

Here we compute the full tidal problem for Mercury, Venus, Earth and Jupiter, the tide-raising planets, taking into account

Fig 1 Tidal potential for the years 1800-08 *a*, Full four-planet tidal potential, *b*, tidal potential excluding Mercury. Both scales are identical

the complete orbital elements, including eccentricity, inclination and their variation with time

At any given time, the tidal potential at a given point *M* on the surface of the Sun caused by the planets is proportional to

$$T = \sum \frac{m_i}{d_i^3} (\cos^2 z_i - \frac{1}{3})$$

where m_i is the mass of the planet, d_i its distance from the centre of the Sun and z_i the angle from the planet to point *M* as seen from the centre of the Sun. We restrict ourselves to Mercury, Venus, Earth and Jupiter. Mars, Saturn and the other outer planets can easily be shown to have trivial contributions compared to the above planets

Table 1 Comparison of tidal and sunspot dates

Tidal peak	Sunspot peak	Dts*
1809	1816	-7

1963	1958	+5
1974	1969	+5

* Dts is the difference between tidal and sunspot peaks in years

Tidal peaks are taken from Fig 2 (and its continuation up to the year 2000). Sunspot peaks are from Wood

In the plane of the ecliptic, the potential depends on the longitude ϕ through a first order polynomial of $\sin 2\phi$ and $\cos 2\phi$. Over a period of 10 d (our sampling interval) the Sun rotates about halfway around its axis and therefore any given point attached to its surface is subject to the whole variation of the tidal potential. So we characterised our problem by the maximum value (over ϕ) of this polynomial. We note that Mercury is the slowest planet around the Sun relative to a point on the Sun's surface and its contribution, contrary to previous arguments³ should therefore not be neglected

The positions of the planets were computed from the best available planetary elements⁴ for 65,536 epochs at intervals of 10 d, or roughly 1,800 yr, starting in the year 1800. A fast Fourier transform (FFT) technique was then used to extract the power spectrum for comparison with the solar activity spectrum

Figure 1 shows the tidal potential as a function of time for the years 1800-1808, both including Mercury (upper trace) and excluding it (lower trace). The high frequency effect is due to the eccentricity of Mercury's orbit and has a period of 0.24 yr

Figure 2, an extension of the lower trace in Fig 1, shows the tidal potential for the 25-yr period 1800-1825, excluding Mercury. The long period, beat-type phenomenon (~ 11.9 yr) arises because of the eccentricity of Jupiter's orbit. By contrast with the sunspot cycle, the tidal pattern repeats almost exactly every 11.9 yr and shows no evidence of a beat of ~ 100 yr. Successive peaks in the tidal envelope are of almost exactly the same amplitude. Wood's samples³ (● in Fig 2) have a spacing too large to provide a valid description of the tidal potential even excluding Mercury, such a sampling leads to aliasing of the lower frequencies. Figure 3 shows the power spectrum obtained from an FFT analysis of the whole 1,800-yr four-planet potential. The fundamental periods are those of the alignments of pairs of planets. Alignments of three, or four planets come as beats of these primary values and consequently do not appear on the spectrum. The periods of Jupiter and Mercury and some of the harmonics show up because of the eccentricity of their orbits. The lower frequency part of the spectrum is very flat, Jupiter being the longest period involved

Fig 2 Three-planet tidal potential for the years 1800-1825 (excluding Mercury). The marks (●) show the points used by Wood³

Figure 4 (frequency scaled) shows an enlargement of the lower frequency part of the spectrum, superimposed with Cohen and Lintz's sunspot spectrum⁵. They showed a strong peak occurring at 11 yr, the familiar sunspot cycle, and smaller peaks at about 9.8, 9.58 and 8.3 yr. In addition they demonstrated that the longer period, ~ 180 -yr cycle proposed for the solar sunspot spectrum arises from the beat of the 11 and 9.8-yr cycles and is not an intrinsic periodicity. This removes the basis for one of the other planetary theories of sunspots⁶. Figure 4 shows no planetary peaks at 8.3, 9.8 or 9.58 yr, peaks which are prominent in the sunspot spectrum⁵.

The origin of the 11.08-yr tidal period claimed by Wood³ is not clear. Such a peak does not appear in our spectrum. In Wood's simplified three-planet system, it could only be the consequence of a Jupiter-Earth-Venus alignment. But if 11.08 yr is indeed a multiple of the Venus-Earth 0.799-yr alignment period, it is not a multiple of the Jupiter-Earth synodic period, and therefore is not a fundamental period of the problem. This discrepancy between the tidal and the sunspot activity periods is further demonstrated in Table 1, which gives sunspot peak dates³ and approximate dates of envelope maxima of the tidal potential, excluding Mercury. The average period between envelope peaks

Fig 3 Power spectrum of tidal potential. The horizontal axis is scaled as $\log T$. The labels on the larger peaks identify the periods (yr) of alignments of planets (two-letter label) or the period of the planets themselves (one-letter label)

Fig 4 Comparison of the lower frequency part of tidal spectrum (b) and sunspot spectrum (a, from ref 5)

is 11.8 yr, the orbital period of Jupiter. From the beginning of the nineteenth century to the present the discrepancy between tidal peak dates and sunspot peak dates has slipped from approximately -7 yr to $+5$ yr. This is the difference between the 11.86-yr Jupiter period and the average sunspot period, 11.05 yr taken over 165 yr (14 cycles). Over a limited period of time, such as 1892 to 1939, the peak years agree to within a year or two but this is to be expected when comparing two periodic functions of nearly the same period. The next tidal envelope maxima occur in 1987 and 1998. In the incomplete tidal theory³ maxima are predicted for 1982, 1993 and 2003.

A further look at our tidal potential values shows no drastic effect expected in 1982 when planets are supposed to align on the same side of the Sun (see ref. 7). Indeed, better alignment will be achieved in 1990. Even then, no special tidal effect occurs because alignment of the outer planets has no pronounced effects on the tides. Alignment of the tide-raising planets within 10 degrees is a common phenomenon, occurring approximately every 10.4 yr and is not associated with drastic tidal effects.

The solar spectrum at 8 mm

THE brightness temperature of the quiet Sun has been measured over almost the complete radio spectrum. It ranges from approximately 6,000 K at millimetre wavelengths to over 10^6 K at metre wavelengths. Various compilations of the disk temperatures¹⁻³ had at centimetre and millimetre wavelengths from 10 to 100 GHz ($\lambda=3$ cm to 3 mm) (Fig. 1). A monotonically decreasing brightness temperature

presented by Shimabukuro and Stacey¹ from a model by van de Hulst⁴ is also shown in Fig. 1. Zheleznyakov⁵ has pointed out that the apparent dip in the observed disk temperatures near 50 GHz and at the apparent peak near 70 GHz, if real, would indicate an effective temperature inversion in the solar chromosphere from 3,000 to 3,300 km above the photosphere. Reber³, however, measured the slope of the brightness against frequency curve at 50 GHz and found that the disk temperature is, in fact, decreasing with increasing frequency in nearly perfect agreement with the van de Hulst⁴ model. Reber's method does not depend on an absolute measurement of the brightness temperature but rather on a relative measurement between two closely spaced frequencies, with a single instrument, thereby giving the slope with more accuracy than can be obtained by comparing a number of independent, absolute measurements.

We have measured the slope of the brightness-frequency curve near 36 GHz ($\lambda=8$ mm) to determine whether the slope best matches the van de Hulst model or the observations.

Fig 1 Solar brightness temperatures against frequency. Triangles represent the measured slope of the curve between 36 GHz and 38 GHz.

The observational method used was similar to that of Reber's³ in which the new Moon is used as a calibration source. The ratio of the brightness temperatures of the Sun and Moon is given by

$$\frac{T_s}{T_M} = \left(\frac{T_A(\text{Sun}) - T_A(\text{sky})}{T_A(\text{Moon}) - T_A(\text{sky})} \right) \quad (1)$$

where T_M = brightness temperature of the Moon, T_s = brightness temperature of the Sun, T_A = measured antenna temperature of the Sun, Moon or sky, provided that the solid angle of the antenna beam is smaller than that of the Sun or Moon, and that all measurements are reduced to the same zenith angle. The Sun-Moon ratio is independent of any knowledge of the antenna gain, atmospheric absorption and re-emission or radiometer calibration constants, provided that those parameters remain constant over an observation.

The ratio T_s/T_M was measured on 21 d within 3 d of new Moon at 36.0 GHz and 37.75 GHz, with a Dicke switched, superheterodyne radiometer. The half power beamwidth was $14'$. Two local oscillators were installed in the radiometer so that the frequency could be switched immediately from 36 GHz to 37.7 GHz. The Sun-new Moon ratios at the two frequencies were found to be 42.6 ± 0.5 at 36 GHz, and 40.6 ± 0.7 at 37.7 GHz.

Using the values for T_M given by Reber³

$$T_s \text{ at } 36 \text{ GHz} = 186 \text{ K} \times 42.6 = 7,920 \pm 90 \text{ K},$$

$$T_s \text{ at } 37.75 \text{ GHz} = 185 \text{ K} \times 40.6 = 7,510 \pm 130 \text{ K}$$

The absolute values of T_s are, of course, subject to the same uncertainties as the absolute value of T_M . The ratio of the two solar temperatures, however, does not have this uncertainty since T_M is nearly constant over the frequency range.

The slope, S , of the brightness curve between two frequencies f_1 and f_2 can be defined as

$$S = \frac{\Delta T_s}{T_s} \frac{f}{\Delta f} = \left\{ 1 - \frac{(T_s/T_M)_{f_2} (T_M)_{f_2}}{(T_s/T_M)_{f_1} (T_M)_{f_1}} \right\} \frac{f_1}{(f_2 - f_1)} \quad (2)$$

where the (T_s/T_M) ratios are determined from equation (1). This definition of slope is the same as the geometric slope of a log-log curve and allows the ratios of the quantities to be used. Substituting the previous values of T_s/T_M for 36.0 GHz and 37.75 GHz into equation (2) gives

$$S = \left(1 - \frac{40.6}{42.6} \times \frac{185}{186} \right) \left(\frac{36}{37.75 - 36} \right) = 1.07 \pm 0.3$$

This result is shown in Fig. 1. Table 1 summarises the slope calculated here, the slope from the van de Hulst model and the slope from the Zheleznyakov model, and gives an estimate of the average slope of the observed disk temperatures from 20 GHz to 40 GHz obtained from Fig. 1.

Table 1 Values obtained for S , the slope of the brightness curve between f_1 and f_2

Observed points 20–40 GHz	$S = 1.4$
Our results	$S = 1.1 \pm 0.3$
Zheleznyakov model ⁵	$S = 1.4$
van de Hulst model ⁴	$S = 0.18$

The steep slope measured at 36 GHz (Table 1) indicates that the observed disk temperatures in the 20–40 GHz range are probably more reliable than the van de Hulst model⁴ calculations. In the centimetre region the observed disk temperatures again join the van de Hulst curve (Fig. 1). There may be a region around 15 GHz where the slope becomes zero, and one would expect no limb brightening to occur. A measurement of the slope between 40 GHz and 50 GHz would determine how the curve blends in with the nearly flat slope found by Reber³ at 50 GHz.

We suggest the future measurements of the solar brightness temperature at millimetre wavelengths should include a measurement of the new Moon. The new Moon serves as a stable calibration source outside the Earth's atmosphere, so that observations of the Sun made with different instruments at different frequencies can be directly compared by considering their Sun to new Moon ratios.

Infrared heterodyne spectroscopy of astronomical and laboratory sources at 8.5 μ

THE first successful infrared heterodyne spectrometer featuring semi-tunable semiconductor diode lasers was constructed and used near 8.5 μ m to make laboratory measurements of line profiles in N_2O and to detect thermal emission from Mars as seen from the Moon. This experiment was conducted at the coude focus of the 30-inch telescope at the Goddard Optical Research Facility in January and February 1974.

In heterodyne detection, infrared radiation (possibly from a remote source) is mixed with the output of an intense coherent local oscillator and a signal is detected at the difference frequency (called the intermediate frequency or if). The spectral characteristics of the remote source are preserved at the if except that the frequency scale is effectively translated by an amount equal to the local oscillator frequency. Using the very best available infrared detectors, and preamplifiers, the bandwidth can extend from close to 'direct current' to above 1 GHz and radio detection techniques may then be used to determine the fine structure of the spectrum of the remote source. The limiting spectral resolution is set by the spread of the local oscillator frequency which for semiconductor diode lasers can be less than 10^5 Hz (ref. 1). Thus, spectral resolutions exceeding 10^8 are possible, far in excess of the resolutions attainable with conventional infrared spectroscopic techniques. Heterodyne spectroscopy is ideally suited for the identification of atomic and molecular species in remote infrared sources and for determination of the line profiles, giving information on the kinetic energy distributions, turbulence conditions, and Doppler velocities of the sources. The extremely high spectral and spatial resolutions make possible the study of low density, low kinetic temperature astronomical sources such as stars, comets, interstellar clouds and the upper atmospheres of planets.

Heterodyne radiometric (non-spectroscopic) methods using gas lasers as local oscillators have recently been successfully applied to detection of broad-band thermal radiation from astronomical sources²⁻⁷ and to laboratory detection of pollutant gases⁸. Although these results demonstrated the feasibility of making such measurements, the real power of heterodyne detection lies in remote spectroscopic measurements at high resolution, long wavelength, and high sensitivity. Peterson *et al.*^{9,10} made the first heterodyne spectroscopic measurements of $C^{18}O_2$ absorption lines in the Mars atmosphere near 11 μ m (see also ref. 10). Their device featured a CO_2 local oscillator and so their observations were limited to the intermediate frequency bandwidth (~ 1 GHz) on either side of the discrete local oscillator frequencies. The versatility of a heterodyne spectrometer is limited by the frequency range over which the laser local oscillator may be tuned and still have sufficient power and coherence for heterodyne operation. Continuously tuneable

Fig. 1 Spectrometer (8.5 μ m) optical system

Fig 2 Comparison of spectral resolution of the heterodyne with other high resolution techniques near 8.5 μm

(over several hundred wave numbers) lasers are not yet commercially available in the middle infrared, but semi-tunable lasers have recently become available.

Cryogenically cooled semi-tunable semiconductor diode lasers^{1,11} have been proposed as possible local oscillators for remote heterodyne measurements of air pollutants by Hinkley and Kelley¹². Diode lasers emitting at nominal wavelengths from 5–34 μm can now be manufactured¹³ and are commercially available (from A. D. Little, Inc.). The nominal wavelength can be preselected by varying the chemical composition of the ternary semiconductor compounds. These lasers generally show multimode output, with mode separations of up to several wave numbers. Each mode can be current tuned continuously over $\sim 1 \text{ cm}^{-1}$ ($\sim 3 \times 10^{10} \text{ Hz}$ at 8.5 μm). Thus, tuning is truly continuous over each single mode and piece-wise continuous over the wave length range of multi-mode operation.

We have built a heterodyne spectrometer using PbSe semiconductor diode lasers as local oscillators, a HgCdTe photodiode as a photomixer¹⁴, and an 8-channel filter bank as a line receiver. The spectrometer was interfaced with a computer controlled 30-inch telescope, and a Dicke type chopper was used to look alternately at the astronomical source and a precision blackbody reference source (Fig 1). An array of four current-tuned diode lasers provided adequate local oscillator power for direct absorption measurements over nearly the entire 1,160 to 1,190 cm^{-1} region, however, the range over which the power was sufficient for heterodyne detection was considerably smaller ($\sim 5 \text{ cm}^{-1}$). The maximum total power output from our best diode was $\sim 2 \text{ mW}$ of which $\sim 100 \text{ μW}$ of single mode coherent power was actually incident on our photomixer.

For heterodyne detection the laser and source signals were superimposed by the beam-splitting lens and focused on to the photomixer (Fig 1). A 200-MHz band at the intermediate frequency output of the photodiode was then fed into the eight-channel filter bank and the output voltage from each 25 MHz channel was linearly converted to a frequency which was counted with a multichannel analyser for the period of integration. Data acquisition was synchronised with the chopping frequency. The measured 1 f noise-equivalent-power (NEP) for our system was $1.5 \times 10^{-19} \text{ W Hz}^{-1}$ at 10.6 μm and 100 μW

local oscillator power. At 8.5 μm and 100 μW the extrapolated NEP is $3.6 \times 10^{-19} \text{ W Hz}^{-1}$. This is a factor of two higher than the theoretical limit $h\nu/\eta$, where η = quantum efficiency) and about a factor of two below the result derived from blackbody measurements at 8.5 μm. Neglecting optical losses and taking into account the marginal laser power, the minimum detectable power for our system for 8-min integration times was $\sim 1 \times 10^{-16} \text{ W}$ in a bandwidth of 25 MHz. The resolving power of our heterodyne spectrometer was 1.4×10^6 .

A comparison of the resolution of our heterodyne spectrometer with other high resolution spectroscopic techniques used to measure remote sources near 8.5 μm is given in Fig 2. A portion of the N_2O spectrum near 8.5 μm is shown along with the resolving bandwidth of the Michelson, tilting filter and heterodyne techniques. Only the heterodyne technique is capable

Fig 3 Heterodyne detection of N_2O absorption line ---, Absorption line profile measured in the direct detection mode. The histogram corresponds to the line profile measured in the heterodyne mode in the eight-channel filter bank.

of line profile measurements of the N_2O lines. Line profiles in the ν_1 band (100–000) of N_2O were measured directly and in the heterodyne mode (Fig 3).

A cell filled with N_2O at 10 torr pressure was placed in position 1 (Fig 1) and the absorption line positions and profiles were determined by direct detection of tuned laser line absorption. The cell was then placed in position 2 and the lines were heterodyne detected in absorption against a 1,300 K blackbody continuum (the optical path to the telescope was blocked). The line was then moved through our filter bank by tuning our local oscillator slightly between measurements. The pressure broadened absorption linewidth was about 170 MHz. For comparison purposes, both lines were normalised to the same amplitude and the direct detected line was drawn at the predicted line centre (PLC) position in the filter bank. The noise is greater in the heterodyne line profile because the blackbody power in a 25 MHz heterodyne channel corresponds to $\sim 10^{-13} \text{ W}$ ($\sim 10^{-14} \text{ W}$ at line centre) whereas the direct measurements correspond to $\sim 10^{-4} \text{ W}$ of laser power at 8.5 μm. We believe that this is the first time that a molecular absorption line profile has been measured using both active and passive measurement techniques.

The heterodyne system was next applied to astronomical observations and was used to measure spectroscopically thermal radiation from Mars and from the Moon (Fig 4). The blackbody continuum near 8.5 μm gave heterodyne signal-to-noise ratios of 3 to 8. The variations were caused by daily changes in the local oscillator power and changing atmospheric conditions. The theoretical system signal-to-noise ratio for a blackbody source is given by^{6,15} where B is the 1 f bandwidth,

$$S/N = \alpha \eta_{\text{eff}} (B \tau^{1/2} / (\exp(h\nu/kT) + 1)) \quad (1)$$

τ the integration time and α the transmission of the atmosphere and optics, η_{eff} is the effective quantum efficiency of our photodiode and is equal to the true quantum efficiency degraded by a factor stemming from the lack of sufficient local oscillator power

Fig 4 Heterodyne signals at 8.5 μm from the Moon and Mars. The signal in each channel is represented by a bar whose height is proportional to the net flux received from the source. The huge signal in the last channel of the lunar data was probably a system noise pulse and was disregarded in determining the signal-to-noise ratio

to reach the shot-noise limit. The true quantum efficiency of our photodiode at 8.5 μm was about 13% and η_{eff} was estimated to lie between 2% and 65% depending on laser operation.

Theoretical signal-to-noise ratios (with $\alpha = 1$ in equation 1) based on local lunar temperature at the region of observations, known electronic parameters, and the appropriate η_{eff} were from 5 to 10 times greater than the experimentally obtained values, implying $\alpha = 0.1 \rightarrow 0.2$. Optical transmission measurements gave $\alpha \approx 0.16$, which is consistent with the range of values obtained by comparing the experimental and theoretical S/N ratios discussed above.

The observed S/N ratios for Mars are more compatible with a temperature of 300 K than the expected value of $\sim 250^\circ\text{K}$ (refs 9, 10 and V. Kunde, private communication). The effective quantum efficiency changed between the measurements of Moon and Mars because of the greater laser output during the Mars run. The quantitative results are of only limited accuracy because of the frequent variation in laser power, poor telescope pointing stability, changes in zenith angle between runs and daily changes in atmospheric conditions. Accurate monitoring of all these parameters was not feasible at the time of the experiments.

The blackbody power from Mars incident on the heterodyne detector in a bandwidth of 25 MHz is $7 \times 10^{-16}\text{ W}$. Conventional techniques are more sensitive for broad-band measurements of blackbody radiation, but spatially localised, narrow spectral lines (with linewidths $\geq 100\text{ MHz}$, say) containing an equivalent energy would be undetectable using conventional techniques. The line profiles most certainly could not be observed. Although our astronomical measurements were not of spectral lines the power detected was of the order expected from remote line sources. The high resolution of our tuneable heterodyne spectrometer (as shown in the laboratory spectral line study) together with its high sensitivity (as demonstrated in the astronomical measurements) make it a suitable instrument for detecting and mapping narrow low intensity spectral lines over a broad wavelength range in the infrared.

Although we were able to obtain heterodyne signals with diode lasers as local oscillators, the measurements were far from straightforward. The coherent output power from presently available diode lasers is generally below that required for shot noise limited heterodyne operation. Because of the characteristics of the diode lasers, great difficulties were encountered in the design of the optical system to collect, focus and match the laser output to our heterodyne field of view. These problems can be eliminated by using better diode lasers and some success has already been achieved in growing more powerful lasers (see, for example, ref 16). The output of the diode laser was sensitive to nearly all environmental effects such as room temperature variations, mechanical and acoustic vibrations, the liquid helium level and the heat sinking parameters of the helium Dewar. The high

resolution of our instrument requires stabilities of better than 0.6 ppm in the focusing optics and the parameters of the diode laser. Meaningful measurements could only be made when the system remained stable during the period of data acquisition. Needless to say, conditions sometimes changed between measurements, making accurate comparisons between runs difficult.

These results demonstrate the capabilities of a heterodyne spectroscopic system and that heterodyning can be achieved using semiconductor diode laser local oscillators. With improved design and better diode lasers future systems should approach the stage at which their operation is limited only by quantum noise.

We thank B. J. Peyton (Airborne Instrument Laboratories) for discussions and for providing the photomixer-preamplifier package, D. Grolemond (RCA-GSFC) and J. Faris (GSFC) for technical assistance, Dr J. Butler (Arthur D. Little, Inc.) for successful efforts to grow better diode lasers, and Dr S. Glicker (GSFC) for preparation of sample gas cells. T. K. was an NAS/Resident Research Associate at the time of this experiment.

Origin of magnetite and pyrrhotite in carbonaceous chondrites

CARBONACEOUS chondrites, although comprising only about 2% of known meteorites, are extremely interesting for scientific investigation. Their mineral constitution, and the correspondence between their bulk chemical composition and the solar abundance of condensable elements, indicate that minimum chemical fractionation and thermal alteration have occurred. The mineral phases observed in these primitive chondrites are sufficiently unique, with respect to other meteorite classes, to have elicited considerable speculation about the physical environment in which they formed¹⁻⁷.

We consider here two minerals—magnetite and pyrrhotite—present in some carbonaceous chondrites and propose that a substantial fraction of the magnetite, at least, resulted from the

oxidation of troilite. Pyrrhotite is expected as a direct consequence of magnetite formation through this reaction. Previously, meteoritic magnetite was considered to have resulted from the oxidation of metallic iron⁸ or from the alteration of olivine⁹. No adequate genesis has been proposed for pyrrhotite¹⁰.

The formation of magnetite from troilite has been observed¹¹ during thermomagnetic analyses—measurement of saturation magnetisation against temperature—on meteoritic troilite. We observed similar behaviour during similar experiments¹² on carbonaceous chondrites and troilite separates from the Staunton iron meteorite, both under vacuum and in a fugacity-controlled atmosphere¹³. As magnetite was observed to form under vacuum, it is evident that troilite reacts with gaseous oxygen, rather than with the gases used for fugacity control. The fact that magnetite formed from troilite on a time scale of minutes prompted us to inquire whether meteoritic magnetite may have formed similarly.

Urey⁸ concluded from thermodynamic arguments that, in an atmosphere with a solar composition of H_2 and H_2S , reaction (1) would proceed to the right below about 700 K. On that basis, meteoritic troilite is usually considered a stable phase below that temperature. The inferred 'stability', however, is relevant only with respect to H_2 and H_2S , to the exclusion of other gases and, therefore, yields no information on the reaction of troilite with O_2 .

Despite the ubiquitous presence of troilite in chondritic meteorites¹⁻⁷, few studies have been made of its stability and the possibility of its oxidation. Above 413 K, troilite converts to hexagonal low-temperature pyrrhotite¹⁴. Taylor¹⁵ has determined the approximate path that pyrrhotite (and presumably troilite) takes on oxidation in air. During oxidation, the sulphide mineral becomes increasingly iron deficient, with the eventual formation of the end member of the oxidation series, pyrite. Apparently, the effective fugacity of sulphur increases (without the addition of that element) whereas the iron activity decreases, the iron being partitioned into the oxide phase.

During thermomagnetic experiments on troilite (some conducted at constant temperature), we observed magnetite formation at temperatures as low as 373 K, provided that the oxygen fugacity was held in the magnetite stability field, and that the troilite was sufficiently finely divided. As expected for a grain-surface reaction, the rate and extent of reaction were strongly dependent on the grain size. Furthermore, we have observed thermomagnetically the formation of pyrrhotite, which confirms Taylor's work¹⁵.

If meteoritic magnetite resulted from the oxidation of troilite then the reaction must have been able to occur under conditions expected in the early Solar System. The petrological evidence must also be compatible with the expected consequences of magnetite formation by that means. Therefore, consider the oxygen fugacity equilibria for three reactions

Since the oxygen fugacity in an atmosphere of solar composition is governed by reaction (2), the oxygen fugacity can be calculated as a function of temperature

$$-\log_{10}(f_{O_2}) = (-2 \Delta G_f^\circ / 2.3RT) - 2 \log_{10}(H_2O/H_2) \quad (5)$$

where the ratio H_2O/H_2 is determined from cosmic abundances¹⁶ and ΔG_f° is taken from thermodynamic data. Oxygen fugacity equilibria for reactions (3) and (4) can also be calculated

$$-\log_{10}(f_{O_2}) = -\Delta G_f^\circ / 2.3nRT \quad (6)$$

using the appropriate thermodynamic data and noting that for

Fig 1 Stability fields of Ni-NiO, Fe-Fe₃O₄ oxygen fugacity and the equilibrium oxygen fugacity expected in an atmosphere with a cosmic abundance of H_2 and H_2O ———, Equilibria of Ni-NiO oxygen fugacity. The NiO stability field lies above this curve, metallic Ni below ———, Equilibria of Fe-Fe₃O₄ oxygen fugacity. The magnetic stability field lies above this line, metallic iron below ———, Oxygen fugacity in an atmosphere with a solar abundance of H_2 and H_2O .

equations (3) and (4), $n = 2$ and $n = \frac{1}{2}$, respectively. For temperatures under consideration here, FeO equilibria can be ignored.

The results of these calculations are shown in Fig 1. Below about 400 K the oxygen fugacity expected in an atmosphere with a solar composition of H_2 and H_2O lies within the magnetic stability field. These calculations demonstrate that provided that equilibrium was maintained, magnetite formation from condensed troilite is possible at temperatures at which we have determined that troilite can readily undergo oxidation. The oxygen fugacity expected in the early Solar System lies well within the metallic nickel stability field at all temperatures. Nickel oxide would not be expected, and any nickel present in the condensate must have existed in a metallic state or in some other chemical form, such as a sulphide.

Next consider the oxidation of meteoritic troilite under conditions expected in the early Solar System. As oxidation progresses, the sulphide mineral becomes iron deficient. Any nickel in the troilite should not oxidise at the oxygen fugacities expected, and, therefore, would remain in the sulphide phase. Thus, the sulphide mineral would become increasingly rich in nickel and increasingly deficient in iron. The degree to which sulphur is partitioned between the sulphide mineral and the gaseous sulphur phase may be a function of the prevailing sulphur fugacity in the system, and is difficult to assess. In a fully condensed system heated as high as about 400 K, the sulphur pressure will depend on whether the system is closed—as expected for subsurface regions of a planetoid—or open (even partially open)—as expected for small porous bodies, for near surface regions of the planetoid, or for material dispersed in space. In an incompletely condensed system, additional complications may arise as a result of sulphur present in the vapour phase. Nonetheless, it is possible to conceive of a fully condensed system subjected to mild heating and open to the loss of the gaseous sulphur phase. Such a system closely approximates the conditions existing during our experimental studies.

If meteoritic magnetite formed from troilite oxidation, as we

suggest, several consequences may be expected (and are observed) in meteorites. From the chemical arguments, discussed here, we expect that any magnetite formed from troilite would contain little nickel, even if the oxidation had been extensive. Magnetite in carbonaceous chondrites has an extremely low Ni content^{13,17}

We also expect the sulphide minerals resulting from troilite oxidation to attest to the degree of oxidation, thus, large grains, subjected to mild oxidation, should form pyrrhotite, somewhat enriched in Ni. Pyrrhotite has been observed in the Orgueil¹⁸ and Revelstoke¹⁹ meteorites, both of which contain abundant magnetite 11.9% and 7.2% respectively¹³. The Ni content of the pyrrhotite phase of Orgueil (~1.0%) is significantly higher than that of meteoritic troilite (~0.2%). Unless an alternative mechanism is found, it seems that the observed pyrrhotite resulted from the oxidation of troilite, which verifies our thesis. Furthermore, extreme oxidation of troilite is expected to result in pyrite formation. The only meteorite in which pyrite has been observed²⁰ is the 'recrystallised' carbonaceous chondrite Karoonda using thermomagnetic measurements we found that it also contains abundant magnetite (7.7%). Finally, the oxidation of troilite may yield a source of SO₂ for the formation of soluble sulphate species observed in carbonaceous chondrites¹. If so, the sulphur in the sulphate phase should be isotopically lighter than the sulphur remaining in the sulphide phase. For Orgueil, at least, that is the case²¹.

We propose that much (if not all) of the magnetite observed in carbonaceous chondrites resulted from troilite oxidation at temperatures ≤ 400 K and that pyrrhotite formation is an expected consequence of this reaction. We have observed experimentally the oxidation of troilite over a time scale ranging from a few minutes to a few hours (depending on grain size and temperature) under conditions similar to those expected in the early Solar System. It seems that the previously inferred 'stability' of troilite in an atmosphere of solar composition, based on reaction (1), is invalidated by the very real possibility of reaction with oxygen. We suggest that further experimental work on the oxidation of troilite, specifically regarding the influence of sulphur fugacity, may yield data useful in establishing constraints on permissible modes of major element condensation and on metamorphic conditions present during the formation of chondritic meteorites.

Detailed structure of a mantle seismic zone using the homogeneous station method

As the accuracy of location of mantle earthquakes has increased, the suggested thickness of seismic zones within the mantle has decreased¹ and special studies are now needed to determine the detailed structure of these zones. In this study we used the homogeneous station method to locate earthquakes occurring at intermediate depths beneath the North Island of New Zealand, and here report that the hypocentres could lie on two dipping surfaces about 9 km apart. Using the plate tectonics hypothesis these surfaces may be related to the top and bottom of a dipping, brittle zone, either down-going oceanic crust^{2,3}, or some colder region within the descending lithosphere⁴.

The intermediate zone under North Island strikes approximately north-west, dips at about 67° to the horizontal and is overlain by the stations of the seismic network run by the Seismological Observatory at Wellington. From the Observatory's readings for the period November 1965-December 1972 (excepting 1970, when readings were unavailable), all subcrustal earthquakes were selected which had P or P-wave phases recorded at seven selected seismic stations (see Fig. 1) and had all but one of these phases recorded to the nearest tenth of a second, the others were recorded to the nearest second. The 73 earthquakes selected, which included 26 with one reading to the nearest second, were relocated using the standard least squares method, the seven P-wave readings, and the Jeffreys-Bullen tables.

The homogeneous station method, which requires that each station records the P-wave phase of each earthquake, is the simplest of the more accurate relative hypocentre location procedures (paper in preparation). The relative mislocation of a pair of events will depend only on the reading errors and the change, from one event to the other, in the model travel time errors—these are the discrepancies between the actual travel times from the true hypocentres to the stations and the times given by the travel-time tables used. Confidence ellipsoids for the relative locations were calculated using time residuals. Fifty-four of the hypocentres within, or close to, the edges of the station network were divided into eight geographical groups, the hypocentres within each group being within a radius of 40 km. If r_{ij} is the time residual of the j th station from the i th event in a group, then we have a model

$$r_{ij} = S_j + \epsilon_{ij}$$

where the S_j s are the mean station residuals for the group and are related to the mean model travel time errors, and the ϵ_{ij} s are related to the reading errors and the variation of the model travel-time errors about their means. We assume the quantities ϵ_{ij} have independent normal distributions with zero mean and a variance σ^2 . The station terms S_j for each group were determined (see Table 1) and a pooled estimate of σ^2 was made for all groups. This gave an estimate of 0.39 s for σ , based on 114 degrees of freedom (54 × 7 residuals - 54 × 4 hypocentral parameters - 8 × 6 station terms). Thus, the 90% confidence ellipses are given by

$$(x, y) A_g^{-1} = 2(0.39)^2 F(2, 114) \quad (1)$$

where A is the appropriate 2 × 2 submatrix of the inverse of the condition matrix of the least squares equations and $F(2, 114)$ is the 90% value of the F distribution.

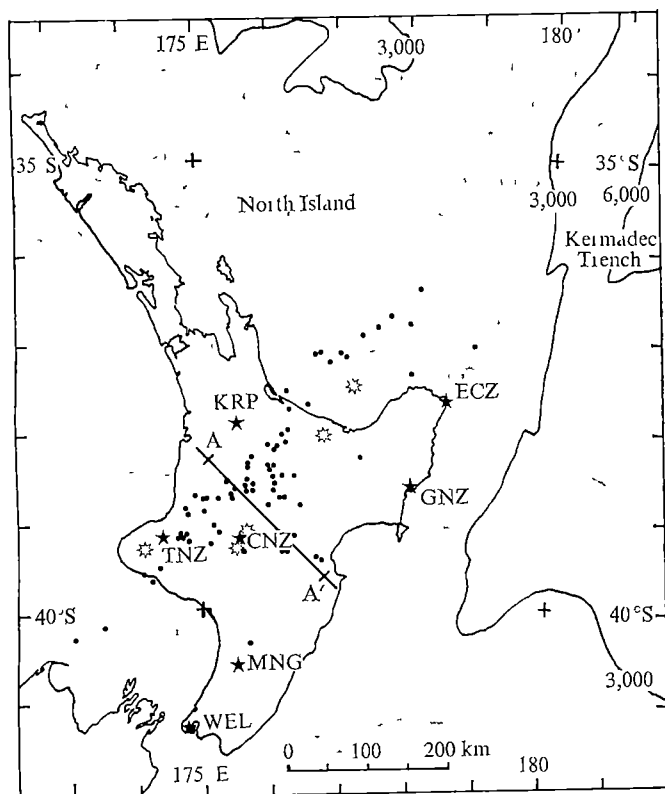

Fig 1 Map and bathymetry of North Island. ●, Epicentres of the earthquakes considered, solid stars, seismic stations used, open stars, active andesite volcanoes. Solid line, depth contours showing depth in metres.

A plane with strike N 45 25° E and dip 67 25° was fitted by the least squares method to all but one of the hypocentres which fall within the net and which were deeper than 118 km. The sum of squares of the perpendicular distances of these 49 hypocentres from the plane was minimised and the standard deviation of the distances was 5.6 km. The Seismological Observatory's hypocentres for the same earthquakes were distributed about a similar plane with a standard deviation of 10.0 km. Hamilton and Gale⁶ fitted median curves to Observatory hypocentres in the same area, and found standard deviations of about 13 km. Clearly, the homogeneous station method locates the hypocentres much more tightly. Typical 90% confidence ellipses in a vertical plane perpendicular to

For location of seismic stations see Fig 1

our plane, and given by equation (1), are shown in Fig 2. The average standard deviation in the direction perpendicular to the plane, based on the estimate of 0.39 for σ , is 3.5 km. Thus, we have good accuracy perpendicular to the zone below about 120 km but not above that depth, where the zone becomes more horizontal. (The earthquake below 118 km excluded from the analysis is isolated and its epicentre is about 38° 3' S, 117° 2' E. Various depth determinations in kilometres are ours 160, the Seismological Observatory's 189, US Coast and Geodetic Survey 114 and International Seismological Centre 100.)

Using the plane of best fit as a reference plane a quadratic surface was fitted to the 49 hypocentres by minimising the sums of the squares of distances from the hypocentres to the surface in the direction perpendicular to the plane. The standard deviation, 4.2 km, was significantly better than that for the plane, but more importantly it was noticed that although most of the hypocentres lay close to the surface, 10 widely spread

Fig 2 Cross section of the seismic zone through AA' (Fig 1), showing hypocentres (●) within 50 km of the section, typical 90% confidence ellipses of relative locations and sections through the best fit plane —, The quadratic surfaces 9 km apart (described in the text), ---, possible extensions of these surfaces

hypocentres were significantly above it in a direction perpendicular to the plane. A quadratic surface was fitted to the larger group of 39 earthquakes and the standard deviation of hypocentres about this surface was 3.4 km—remarkably close to the value of 3.5 km obtained independently from the residual analysis. The remaining 10 hypocentres had a mean displacement of 8.8 km from the surface (perpendicular to the plane). The standard deviation about their mean was 1.5 km, but this low figure probably results from the biased sampling technique. The histogram of distances from the surface is shown in

Fig. 3 Histogram of distances of hypocentres from the lower quadratic surface (see text), and the predicted distribution of 39 hypocentres on the surface of the plane and 10 hypocentres 8.8 km above the surface of the plane, with normal distributions and standard deviations about their means of 3.5 km

Fig. 3 together with the predicted distribution for 39 hypocentres on the surface of the plane, and 10 hypocentres 8.8 km above the surface of the plane, with normal distributions and standard deviations of 3.5 km about the means in both cases. The evidence suggests strongly that the North Island deep seismic zone is about 9 km thick and that the earthquakes initiate in the top and bottom surfaces of the zone. Mechanism studies⁶ show no clear differences between earthquakes originating on either surface, and our results differ, therefore, from those from the Kurile Islands⁷ where there is a 30 km thick zone with differing earthquake mechanisms above and below. Further studies are to be done to locate less well recorded earthquakes and to improve the absolute locations.

Possible large creep event apparently preceded by a dilatant precursor

THE invar wire earth strainmeter at the Nelson underground field station of the Physics and Engineering Laboratory, New Zealand, has produced the record shown in Fig. 1. The size of the two strain steps shown was far too great to be recorded on the tidal chart recorder but have been established with complete confidence from the amount of mechanical adjustment needed at the time of the inspection visits. Long term invar expansion has been removed from the curve shown. This is measured independently on an identical instrument decoupled from the earth using a sample of the same wire held at the same temperature and tension, but referred to very old large diameter Pyrex glass tubes as a reference length. Ideally, these should be of fused silica. The equation of the long term expansion agrees quite closely with that reported by Kaye¹ in 1911.

There were no earthquakes at the times of the two events shown and it is postulated that the strain change of 1.2×10^{-4} was produced by a large creep of about 20 cm, possibly on the nearby Waimea fault. On the surface this lies 5 km from the station but the creep was perhaps deep and without surface expression. In contrast to California, most seismic events in New Zealand do not correlate well with known active faults² and this event may be no exception. The apparent precursor about 20 months before would, if caused by rock dilatancy, indicate an earthquake of about magnitude 6 (ref. 3), but instead an aseismic creep event occurred. Work by Chinnery⁴ indicates that a 20 cm displacement is of the order to be expected from an earthquake of magnitude 6. The second much smaller event is regarded as an 'after-creep' of the first.

Fig. 1 Long term earth strain record from Nelson underground field station (41° 5' S, 172° 9' E, 150 m deep) from the time recording began in July 1971. The installation of the instrument⁶ was carried out in early February 1971. The curve has been derived both from measurements at the time of the inspection visits and from the high sensitivity chart recorder which has an automatic stepper giving an effective range of approximately 70 chart widths.

Wire tension increased at the time of each event and therefore they can hardly be attributed to instrumental defects. No other comparable events have been recorded on two other strainmeters of the same design which have been operating at other distant stations for similar periods of time. There is also a difference in the rate of strain accumulation before and after the event. Extrapolation of the present rate would indicate another such event in approximately 20-25 yr which, of course, might then appear as an earthquake. It is interesting that in 1941 there was an earthquake of magnitude 5.5 at just this location⁵ (41° 6' S, 172° 9' E), although at a depth of 80 km.

I thank Dr R. G. Bilham of the University of Cambridge for valuable comments on the probable reality of this event.

Mechanism for the persistence of tectonic lineaments

It is widely recognised that major faults and other linear zones of tectonic activity may remain intermittently active through extended periods of geological time. I suggest a mechanism which may account for this persistence.

Examples of long lived linear tectonic belts are known in most continents although their significance was probably

first appreciated in the Soviet Union where activity on the deep faults bordering the southern margin of the Siberian shield is known to extend from Archaean to late Phanerozoic times¹⁻³. In Africa the present rift zone has been identified as the locus of Precambrian activity⁴, and Precambrian lineaments in the West African and Guyana shields were reactivated during the Mesozoic separation of Africa and South America⁵.

Two of the major Precambrian boundaries in Greenland have been shown to have remained active for up to 1,000 Myr from their initiation in the Archaean⁶, and more recent work on the Nagssugtoqidian boundary has extended the probable period of intermittent activity to 2,500 Myr. The earliest recognised activity at this boundary is large scale ductile transcurrent movement along⁷ a vertical shear belt, 35 to 40 km wide, along which movement began about 2,650 Myr ago. Following further activity in the Precambrian, the boundary region was the locus of intrusion of a suite of kimberlite and associated dykes of Cambrian age⁷. The suggestion that movements continued during the Phanerozoic⁸, based on the possibility of pseudotachylites cutting dykes of the kimberlite suite, has since been confirmed (J. Grocott, personal communication). Offshore seismic work in connection with hydrocarbon prospecting has shown faulting or fault controlled deposition of Mesozoic sediments along the line of the Precambrian shear zone. This not only confirms that the lineament has remained intermittently active for more than half of the Earth's history, but also illustrates the economic significance of such lineaments.

Any explanation for the persistence of activity along a major linear movement zone is subject to two principal constraints. The persistence of activity must be provoked within the lithosphere because, over the time scale considered, no part of the lithosphere is likely to have remained fixed in position relative to underlying mantle. On the other hand, translation of plates and displacements within them result from causes external to the lithosphere. Both these requirements are met if a lineament is the expression of a persisting mechanical weakness, along which displacements which otherwise would be more widely distributed have been localised. If that is the case a lineament is likely to accommodate a variety of movement directions during its active life. An appropriate mechanical weakness would be one affecting a major part of the thickness of a lithospheric plate and would not be restricted to the relatively thin upper portion where brittle fracture is dominant in rock failure and displacement.

The significance of large scale zones of ductile simple shear strain has become apparent recently^{9,10}. In particular, it is clear that they are the deeper and mostly aseismic continuations of structures which appear at higher crustal levels as major faults, thrusts, and brittle fracture zones. A characteristic of ductile shear zones, most easily seen in small scale examples up to a few metres wide, is that the deformation, although plastic, is usually accompanied by a reduction in grain size. Theoretical and experimental studies^{11,12} suggest that grain size is a significant variable in determining rates of plastic deformation, because of the predominant role of grain boundary diffusion in deformation at high temperature and low stress. A theoretical model in which strain rate varies in inverse proportion to grain diameter¹³ is in substantial agreement with strain rate experiments on the deformation of marble at high temperature¹⁴. Other theoretical studies indicate the importance of grain size in determining creep rates¹⁵. An acceleration of strain rates is to be expected towards the centre of ductile shear zones where, because of boundary effects, initial strains are highest and the initial reduction in grain size most marked. In a rock mass which is anisotropic in respect of grain size, and hence ductility, the application of deviatoric stresses will produce strain along suitably oriented

existing planes of finer grained and more ductile rock—those zones along which previous ductile displacement took place without subsequent recovery of grain size by grain growth. It is then important to determine whether or not planar zones of finer grained rock, seen at present levels of erosion in Precambrian basement rocks as ductile shear zones, extend through an appreciable thickness of the lithospheric plate. The scale of transcurrent displacements along major lineaments, whether now observed as brittle faults or ductile shears, is commonly of the order of tens or hundreds of kilometres and difficult to account for otherwise than by extension of the displacement downwards as far as the decoupled zone at the base of the lithosphere. The identification of intense tectonic fabrics in upper mantle rocks now seen as inclusions in kimberlites, dykes and pipes is particularly interesting. These fabrics have been particularly well demonstrated in a series of deformed mantle rocks from kimberlites in Lesotho¹⁶. Comparable fabrics exist, although less well developed, in the kimberlites from the Nagssugtoqidian boundary. Such examples, with textures identical with those of deformed crustal rocks, show the similarity of deformation processes at widely separated levels within the lithosphere, and demonstrate that ductility increase by grain size reduction can reasonably be regarded as likely to be effective on the scale of the lithospheric plate. Such weakening can only be responsible for the persistence of lineaments if recovery of grain size by grain growth is not effected in the time interval between successive increments of movement along the lineament. Recovery times are certainly very prolonged in crustal rocks as evidenced by the ubiquity of grain size anisotropy in tectonites, and by the absence of grain growth fabrics in the inclusions from both Lesotho and Greenland kimberlites, which suggests that the rates of recovery of grain size in mantle rocks are also slow relative to strain rates.

So I suggest that the concept of mechanical weakening through reduction in grain size may account for the longevity of major tectonic lineaments, this proposal can be tested by work on the fabrics of crustal and mantle tectonites, and on annealing rates. Future work should also show whether the distribution of tectonised mantle inclusions in kimberlites is related to tectonic lineaments, or whether kimberlite distributions are related to such lineaments as seems to be the case on the Nagssugtoqidian boundary and has been suggested for kimberlites in Southern Africa¹⁷ and Siberia¹⁸.

I emphasise that these proposals are complementary to current plate tectonic theory, plate boundaries initiated in recent geological time (the late Phanerozoic), in several cases seem to coincide with older lineaments.

Work on the Nagssugtoqidian boundary is supported by the Natural Environment Research Council and carried out with the cooperation of the Geological Survey of Greenland.

The February–June weather relationship in north-west Europe

It has been well said by Bonacina¹ that everything which happens to, or in, the atmosphere, affects its subsequent behaviour. In other words, there is a "memory" in the atmosphere, probably such that an anomaly produced at one time may lead to a similar, or a related, anomaly being restored in the future. It is known that although some factors can be neglected for short range forecasting, they become progressively more important in the longer range. These factors are unknown, although most meteorologists would probably agree with Namias² that two of the most important must be extraterrestrial events, such as variations in solar activity, and variations in the character of the Earth's surface.

But empirical methods of long range forecasting are sometimes found simply by discovering relationships between observations at different times and places, and there seems no reason for not using them in prediction. The physical mechanism behind the relationship may not be fully understood, but the empirical discovery usually points to the research required for understanding the mechanism. Here I illustrate this idea by an example.

In the course of looking at climatic trends in north-west Europe, particularly the northern North Sea area, certain relationships were noted between weekly or monthly periods in the winter season and periods of similar length in the following summer. This may best be illustrated by what one may call the February–June relationship. Figure 1 shows the

* Almost the same as previous year

relationship between February and June from 1940 onwards for Dalen 1 Telemark (59°27'N, 8°0'E), an inland station in southern Norway. A regression line can be drawn which shows that the mean temperature in February is inversely related to the mean temperature in June. If this regression line is used at the end of February to estimate the mean temperature for the following June, the results compare very favourably with the actual temperatures (Table 1).

It will be seen that in 30 years out of 35 the estimate was correct in the sense that it predicted correctly whether the June mean temperature would be higher or lower than (or very nearly the same as) that of the previous year. In 25 years out of 35 the mean temperature was predicted correctly to within 1.0° C and in 14 of those years it was correct to within 0.5° C. The accuracy of the estimates increased until the past few years, when it has deteriorated slightly. Some variations in this simple predictive method were investigated, mainly to try to take into account year-to-year trends, but this has not led to any general improvement in the method.

Periods other than calendar months were not used because of the greater amount of work involved. Had this been done, it would have rectified some, if not all, of the least successful predictions. For example, the prediction of a very warm June in 1955 proved to be incorrect, but in fact July proved to be exceptionally hot.

This February–June relationship was explored (1) backwards in time, and (2) in neighbouring areas. At Dalen 1 Telemark, during most of the 1940s, the relationship came close to the regression, but this was not the case from 1891 to the 1940s. There was, however, a suggestion of two populations, one with a direct correlation and another with an inverse correlation, the latter applying to all cases where the February mean temperature was -6.0°C or below. Examination of other stations in Norway, Denmark, Scotland and England indicated that the inverse correlation between February and

June mean temperatures had been spreading south and west. There is more scatter about the regression line at coastal stations, but, for practical purposes this is compensated for by the angle of slope of the regression line approaching 45° .

In both Norway and Scotland, higher than average temperatures in winter correlate well with higher than average rainfall, since both occur in westerly and cyclonic conditions. Conversely, there is relatively little precipitation in anticyclonic conditions. In summer there is an inverse relationship between temperature and rainfall. Thus forecasting temperature is almost tantamount to forecasting approximate rainfall. In the case of Bergen, Norway, in 22 consecutive years out of 23, June rainfalls were correctly predicted at least to the extent of being greater or less than in the preceding year, and in 13 years out of 25 the amount was predicted to within 25% (Table 2).

Mean February temperatures from Dalen i Telemark were used to predict mean June temperatures and rainfall from 1954 onwards for Kinlochewe, in Wester Ross. For temperature, the predictions were nearly as good as when February temperatures for Kinlochewe were used, but for rainfall they were usually better (Table 3). The particular case of 1974 is interesting. February was mild, and followed a quite exceptionally mild January. The predicted rainfall for June was 165 mm. In the event, the June rainfall was only 69.6 mm at Kinlochewe, but there was a very marked spell of wet weather, preceded and followed by dry conditions, commencing on May 18, the rainfall for this period was 164.6 mm, suggesting that the very mild and wet period in January–February was preconditioning a wet spell in May–June.

The meaning and physical explanation of this empirical prediction technique can only be guessed at. The second of Namias' factors—variations in the character of the land or sea surface—may be a more direct key to the relationships described than is the extraterrestrial factor. Can one determine, for instance, what was the particular state of which part of the Earth's surface in successive Februaries which injected a factor into the atmospheric circulation that was effective in inducing another particular condition the following June? It is not unreasonable to suppose that the surface conditions in February reflect the dominating influence which has characterised the whole winter.

Two significant factors which come to mind are (1) the generally accepted spread southwards of the Arctic high pressure

area, and (2) the related decrease in westerly days in the zone to the south of this. It is significant that Trondheim, the northernmost station considered, showed the inverse February–June correlation earliest, and that it became recognisable further south and west as time went on. This implies increasing anticyclonic control of the relationship. Markedly anticyclonic and cold Februaries in Norway have almost invariably preceded warm Junes, and since well before the 1940s, but in addition it seems that milder, westerly Februaries now precede cool wet Junes more regularly than they used to.

In view of the very limited success of the methods at present used by the Meteorological Office in producing monthly weather outlooks³ I feel that studies of the type described here could be very useful ingredients in the development of long-range forecasting technique, especially when correlated with the *Grosswetter Lager* and other atmospheric circulation studies. I am pursuing this matter, with some success, in cases other than the February–June relationship.

I thank Dr E. M. Frisby for many suggestions during the course of this study, and the Norwegian Meteorological Institute for the provision of observational data in advance of publication.

Molecular complexity of water vapour and the speed of sound

EVIDENCE has been given for a high binding energy of dimerisation in water vapour deduced from measurements of the speed of sound¹. The quoted value of 0.5 eV per molecule must be reconciled with values of about 0.2 eV per molecule which have been derived both from thermodynamic measurements² and from molecular orbital calculations³. We are interested in the behaviour of tropospheric water vapour, so we made observations at lower temperatures than the PVT and calorimetric observations which were relevant to steam technology. We

Fig. 1. $[(v_0 - v)/v_0 P] kT$ plotted against temperature. A two-dimer model fitted to the observations is represented by the solid line, for comparison, the dotted line is derived from published calorimetric measurements made in the temperature range 312–398 K. The points with error bars are derived from speed of sound measurements.

have now extended the temperature range of the speed of sound observations to cover the interval from 289 to 353 K.

Figure 1 shows values of the quantity $[(v_0 - v)/v_0 P] kT$ plotted against temperature T , where k is Boltzmann's constant. At each temperature the value of $(v_0 - v)/P$ was determined from the slope, and that of v_0 from the intercept of the straight line representing the observed speed of sound, v , against pressure, P .

Virial coefficients are used as the basis of the comparison of results, and are related to speed of sound by the expression⁴

$$\frac{(v_0 - v)}{v_0 P} kT = - \left[B + B'T(\gamma_0 - 1) + B''T^2 \frac{(\gamma_0 - 1)^2}{2\gamma_0} \right] \quad (1)$$

where B is the second virial coefficient, the primes denote differentiation with respect to temperature, and γ_0 is the ratio of specific heats for water at the limit of zero pressure. We take γ_0 to have the value 1.32. Only binary interactions have been considered, as within the limits of experimental error we have observed that changes in the speed of sound at a given temperature are linearly proportional to changes in pressure.

Published values of virial coefficients for water have been reviewed critically by Wexler and Greenspan⁵ and we have chosen for comparison those derived by Goff and Gratch⁶ from calorimetric measurements^{7,8} made in the temperature range

Table 1 Second virial coefficients (cm^3 per molecule)

	289 K	312 K	353 K
B_1 (Berthelot)	-8.3×10^{-22}	-7.0×10^{-22}	-5.4×10^{-22}
B_{2a}	-1.4×10^{-21}	-8.8×10^{-22}	-4.5×10^{-22}
B_{2b}	-2.8×10^{-22}	-5.1×10^{-24}	-1.4×10^{-26}
$B = B_1 + B_{2a} + B_{2b}$ (present work)	-2.5×10^{-21}	-1.6×10^{-21}	-9.9×10^{-22}
B (ref. 6)	-2.3×10^{-21}	-1.6×10^{-21}	-9.3×10^{-22}

from 312 to 398 K. The dotted curve in Fig. 1 is a plot of the function given by the right hand side of equation (1) using the empirical formula for the second virial coefficient, found by Goff and Gratch, to give the best fit to the calorimetric data. At temperatures where our observations overlap with the calorimetric data they lie close to the line but at lower temperatures they depart considerably from it.

The second virial coefficient, B , has been represented² as the sum of a dimerisation term, B_2 , and a term, B_1 , attributed to non-polar van der Waals' type attractions. Berthelot's formula allows B_1 to be calculated and for that formula we take the values of the critical temperature and pressure given by Rowlinson². For B_2 we use the expression

$$B_2 = - \frac{N_2}{N_1^2} = - \sigma \exp\left(-\frac{E}{kT}\right) \quad (2)$$

where N_1 is the concentration of monomers, N_2 of dimers, and $-E$ is the dimer binding energy. σ is a scale factor for dimer concentration, related to the partition functions of monomer and dimer, and is taken to have negligible variation with temperature. The Rowlinson formulation of the second virial coefficient with the values $-E = 0.17$ eV per molecule, and $\sigma = 1.4 \times 10^{-24}$ cm^3 per molecule gives a good fit to the calorimetric data.

To account for the speed of sound at low temperatures we have used a model for water vapour in which B_2 is itself the sum of two terms B_{2a} and B_{2b} , each applying to a species of dimer with a characteristic binding energy and scale factor. The full line in Fig. 1 represents a calculation using equation (1) and $B = B_1 + B_{2a} + B_{2b}$, with

$$\begin{aligned} -E_a &= 0.16 \pm 0.09 \text{ eV per molecule } (\sigma_a \sim 10^{-24} \text{ cm}^3 \text{ per molecule}) \\ -E_b &= 1.4 \pm 0.3 \text{ eV per molecule } (\sigma_b \sim 10^{-45} \text{ cm}^3 \text{ per molecule}) \end{aligned}$$

These were found by least squares analysis to give the best fit of the curve to our observations. Representative values of the second virial coefficient and its components are given in Table 1. In the temperature range we have studied, the values of B do not depart by more than the experimental uncertainty from values calculated from the empirical formula of Goff and Gratch⁶. At low temperatures, the significant difference between the two curves in Fig. 1 may be attributed instead to large values of $-B_{2b}$.

The binding energy of 0.5 eV per molecule given in the preliminary analysis in which only a single species was considered, is now explicable as a weighted average of the binding energies of two species of dimer. In our new analysis, values for the binding energy and the corresponding scale factor for one species are substantially in agreement with those of the familiar low binding energy dimer cited in the introduction. Comparing values of B_{2b} with those of B_{2a} we find that at 289 K the concentration of the high binding energy dimer is about 20% that of the low binding energy species. This indication of an appreciable concentration of dimers with a high binding energy is a provocative result which will need further investigation. We note that it applies to adiabatic conditions given by sound pulses which in our experiment had a duration of about 20 μs .

Fusion ignition of microfission explosions

WINTERBERG¹ proposed that microexplosions could be caused in very small amounts of fissionable materials such as ²³³U, ²³⁵U, and ²³⁹Pu (see also refs 2 and 3). A small critical mass could be created by imploding the fissionable material until it was 200-300 times its normal density. This could be achieved using a high energy, properly shaped laser pulse (of about 1 ns duration). For a chain reaction to begin in the assembled critical mass, however, neutrons must be present to initiate the fission process. For a critical mass of uranium, of 0.34 g, and a hydrodynamic disassembly time of 10⁻⁹ s, as proposed by Winterberg¹, conventional neutron sources will not be adequate to initiate a chain reaction. Initiation of the fission process using neutrons produced from the fusion of a deuterium-tritium (D-T) mixture placed in the core of the fissionable material seems feasible and offers several distinct advantages over conventional neutron sources.

As far as conventional neutron sources are concerned, a beryllium- α source of sufficient strength to initiate a chain reaction within of the order of 1 ns would be too large to fit within the uranium sphere (it would have an initial radius of 0.16 cm). For example, Hanson⁴ gives strengths of the order of 2×10^7 neutrons s⁻¹ g⁻¹ of radium for Ra- α -n sources. To produce a neutron source strong enough to average 1 neutron ns⁻¹ (the hydrodynamic disassembly time) would take approximately 50 g of radium. Use of radon gas as an α source would require about 0.7 g of radon, which is still clearly unacceptable.

Other possible sources of neutrons, such as a Triga pulsed reactor, or a pulsed accelerator using a ⁹Be(d,n) reaction, would also be inadequate since, even if a high enough neutron flux could be achieved, the neutrons would strike the compressed pellet from the outside. That would be likely to initiate fission in the outer portions of the spherical mass before the desired degree of super-criticality had been reached, thus causing premature or non-uniform detonation, resulting in a fizzle yield.

As an alternative to these conventional neutron sources, a small amount of a D-T mixture could be embedded in the core of the sphere of fissionable material. Compression of the D-T core would induce thermonuclear fusion and produce 14 MeV neutrons according to the reaction

Neutrons from this reaction have been produced⁵ by the compression of a D-T pellet with a laser pulse. The rate of neutron production^{6,7} from this reaction is

$$dN/dt = N_D N_T (\bar{\sigma v})_{DT}$$

$$\text{where } N_D \simeq 2 \times 10^{26} \text{ cm}^{-3}$$

$$N_T \simeq 2 \times 10^{26} \text{ cm}^{-3} \quad (2)$$

$$(\bar{\sigma v})_{DT} \simeq 10^{-21} \text{ cm}^3 \text{ s}^{-1}$$

are the deuterium number density, tritium number density and Maxwell-Boltzmann average of the product of

the cross section and velocity, respectively. A D-T mixture occupying 10⁻⁶ of the volume of the sphere of fissionable material gives 10¹² neutrons in 10⁻¹¹ s (the approximate neutron doubling time in the fission reaction). So the D-T fusion reaction will produce copious quantities of neutrons in the necessary time interval, and will initiate the fission reaction.

There are many advantages to this technique of initiating fusion. First, having the D-T mixture in the core of the spherical critical mass makes the initial neutron density highest at the centre of the sphere. It decreases radially outward, leading to an efficient chain reaction which develops from the middle towards the edges. Second, at the centre of the sphere there would be a pressure spike from the implosion of the sphere to critical mass, this higher pressure (and density) would make the production of neutrons by D-T fusion more efficient. Finally, since the core would be the last part of the sphere to be compressed, no neutrons would be produced until a critical (or super critical) mass was achieved. That would lead to high efficiency and would avoid the problems of a fizzle yield.

Dissolution of powdered quartz

POWDERED quartz exhibits an initially high solubility rate but opinions are divided as to the cause. Clelland¹ argued in favour of the 'Beilby layer'—a skin of vitreous material produced during grinding, whereas Talbot² stated that the numerous small particles which were always found adhering to the larger particles of quartz offered a plausible explanation.

The fraction of quartz detectable by differential thermal analysis (DTA) becomes less³ during grinding, but the fraction can be restored to 100% by etching with hydrofluoric acid. This has been attributed to the dissolution of amorphous layers from the surfaces of the particles, leaving behind crystalline quartz. We show here, however, that when the fraction of quartz detectable by DTA is increased as a result of etching in hydrofluoric acid, the material which dissolves is crystalline and not amorphous.

A quartz sand from Chatteris, Cambridgeshire, produced a characteristic DTA inversion peak (Fig 1a). The quartz sand was milled for 400 h in a vibration mill with a steel body containing steel balls, and iron contaminant was removed from the resultant powder using hydrochloric acid. The purified material produced a curve with a greatly reduced DTA inversion peak (Fig 1b). The material was then subjected to two different treatments.

The first involved etching in dilute hydrofluoric acid which resulted in the dissolution of 30% by weight of the material. The residue was collected by centrifugation and produced a DTA curve with a larger inversion peak (Fig 1c).

The second treatment involved separating the powder into a coarse and a fine fraction by dispersing the quartz in dilute hydrochloric acid (quartz is less soluble in hydrochloric acid than in water and is easier to disperse) and centrifuging the suspension to obtain a precipitate of the

coarser material, leaving the finer material in suspension. The process of dispersal and centrifugation was repeated until 30% by weight of finer material had been separated out. The coarse fraction thus obtained was subjected to DTA, and produced a curve with an inversion peak that had increased in size (Fig 1d) compared with the original material (Fig 1b) but, which was, perhaps, not so large as that produced by the etched quartz (Fig 1c).

Fig 1 Differential thermal analysis curves of an 0.285 g sample of powdered quartz heated at $20^{\circ}\text{C min}^{-1}$. a, original quartz sand, b, after grinding for a duration of 400 h, c, ground material from b after etching, d, ground material from b after the fines had been removed by sedimentation.

The fine material was subjected to two tests. First, it was suspended in hydrofluoric acid of the same strength as that used during etching. It dissolved completely within the time that had been allowed for the etching treatment. Second, a small quantity of the finest material obtained (less than $0.1\text{ }\mu\text{m}$ Stoke's diameter) was tested by X-ray diffraction (Fig 2a) and found to consist substantially of crystalline quartz. A reference picture (Fig 2b) for quartz milled for 3 h is also given. The fine material, shows a small amount of line broadening, but displays peak intensities almost equal to that of the reference sample.

Since the fine material dissolved completely within the time previously allotted for etching, it seems that similar fine material must have been removed by the hydrofluoric acid, leaving behind the larger particles of quartz. Furthermore, these fine particles must consist substantially of crystalline quartz (Fig 2a and b) and are therefore not amorphous. Thus, since the removal of fine particles by sedimentation resulted in a larger DTA peak, the increase in size of DTA peak as a result of etching the powder in hydrofluoric acid must to some extent be caused by the removal of fine particles which dissolve during the etching treatment.

Does the inversion peak produced by the etched material, which is larger than that produced by the coarse material obtained by sedimentation, leave a margin of uncertainty which could be explicable in terms of the dissolution of an amorphous layer? There are three answers to this question.

First, the processes of removing finer material by sedimentation and by etching cannot be assumed to be exactly equivalent. The powder is very difficult to disperse and sedimentation allows some very fine particles to remain attached to the larger ones. Furthermore, there is evidence (G S M M and H E R, unpublished) that during the grinding of quartz, 'internal subdivision' occurs resulting in the formation of grains within each particle. Such a system would be very difficult to disperse but finer grains and particles would not escape more rapid dissolution in hydrofluoric acid.

Second, the grinding of the quartz could produce residual strain within the particles. The inversion temperature of quartz is a function of pressure, and residual strain could cause the DTA inversion peak to be less pronounced if the inversion is spread over a range of temperature as a result of residual strain. When etched in hydrofluoric acid, the removal of the material under a state of strain, presumably more soluble in this condition, could produce a release of strain from the remaining quartz thus causing a more pronounced DTA inversion peak.

Third, we have found that, according to the results of density measurements, there is no evidence that amorphous material is produced, even when the quartz had been dry ground for several hundred hours, until crystalline quartz could not be detected by DTA.

The density of the powder, after corrections for absorbed atmospheric moisture and impurities, remained at 2.65 g ml^{-1} during grinding, and X-ray diffraction confirmed that the powder had a crystalline structure corresponding to that of quartz. Thus, although the quartz remained in a crystalline condition during grinding, it was apparent that the inversion characteristics had become so modified that the DTA inversion peak at 573°C , normally characteristic of quartz, had disappeared. So, it seems that during etching, this finely divided quartz which we have referred to as

Fig 2 Photodensitometer traverses of X-ray film a, material with a particle size less than $0.1\text{ }\mu\text{m}$ extracted from quartz ground for 400 h, b, a reference curve of quartz milled for 3 h. Cu $K\alpha$ radiation, Ni filter.

of females might be genetically too inflexible. The extreme in maximisation of brood space would be for all members of the population to produce eggs, some or all of them producing sperm also. (Carlquist¹⁰ reasons similarly regarding gynodioecious plants.)

This last possibility, simultaneous hermaphroditism, occurs in the only other species of externally-brooding actinian to have been studied¹¹, called *E. prolifera* at that time, this species is now identified as *E. japonica* (T. Uchida, personal communication). Selection against sperm production beyond what is necessary to fertilise sufficient ova to fill the brood space by restricting it to certain members of the population is a possible evolutionary pathway from simultaneous to gynodioecious hermaphroditism. The larger anemones might have been favoured as sperm-producers since they had proved best adapted by virtue of their longevity, and because proportionately less of the energy and material budgeted for gametes could be used by them for sperm than by smaller animals.

Developmental gynodioecy in self fertile species would favour reproduction by only the fittest colonists of new habitats, maximising the chances of survival of succeeding generations. If a hermaphrodite were the founder, it could begin to establish a population immediately. If the animal had not yet attained hermaphroditism, it could begin to reproduce successfully only after having proved its fitness for the new circumstances by surviving in them. Even assuming *E. prolifera* can self, however, it must rarely survive being swept into a new site, so this advantage probably had little to do with the evolution of gynodioecy in this species.

Developmental gynodioecy is an adaptable breeding system. Theoretically, the genetic diversity of gametes is as great as in simultaneous hermaphrodites because virtually all individuals eventually produce sperm as well as ova. Excessive sperm production can be prevented by evolutionary adjustment of the time of onset and extent of testicular development to optimise the sperm:egg ratio of the population. At any one time, the same ratio can be attained as in dioecious species but with greater genetic diversity of sperm because more hermaphrodites are required to produce as many sperm as can be produced by a given number of purely male individuals of the same size.

The genetically-fixed gynodioecy of plants apparently evolved as a mechanism for enhancing outbreeding among normally self fertile hermaphrodites. The developmental gynodioecy of *Epiactis prolifera* probably evolved as a means of increasing the number of brooders (egg-producers) in a population with limited fecundity to a maximum, and possibly also of enhancing inbreeding among normally cross fertile individuals.

Evidence for a Y chromosomal contribution to an aggressive phenotype in inbred mice

IN man the XYY chromosome complement has been reported by some authors to be associated with abnormal tallness, mental deficiency and sociopathic, aggressive behaviour¹⁻⁴. The interpretation of this literature is controversial. Furthermore, any genetic variation(s) of the Y chromosome which affect(s) aggressive behaviour among chromosomally normal males could mask the correlation between a supernumerary Y and this behaviour⁵. If such variation exists, then in any population the correlation between the XYY karyotype and aggression would depend on the distribution of Y chromosomes having varying degrees of predisposition towards aggressive behaviour. Our investigations on the developmental genetics of fighting behaviour in mice support the hypothesis that there may be heritable variations of the Y chromosome which are associated to varying degrees with some types of aggression, and that this could account both for the lack of unusual aggressive behaviour in many individuals with an extra Y and for its occurrence in other XYY males.

In an initial study, one of us⁶ showed that male DBA/1/Bg mice were more aggressive than C57BL/10/Bg males and that in their reciprocal hybrids, those F₁ males sired by DBA/1/Bg were more aggressive than those sired by C57BL/10/Bg. These findings, suggested to us that the Y chromosome of the DBA/1/Bg makes an incremental contribution to intermale aggressiveness. We report here the original data⁶ and a replication entailing a larger sample.

Intraspecific aggression was measured in encounters between pairs of male mice isolated from the time of weaning at 29 d of age until testing at 50 d of age when they were sexually mature. Pasteurised food and water were available *ad libitum*. Water was acidified (pH 2.5) and chlorinated (12-18 p.p.m.). Lighting was on a 12 h light: 12 h dark diurnal cycle with lights on at 0600. The mice were tested in a laboratory cage (16 × 26.5 × 11.5 cm) covered by a 6.4 mm wire mesh. The cage was divided by an opaque partition. Subject animals were placed on either side of the partition which was removed after a 5-min adaptation period. Trials were limited to 10 min during which behavioural records were kept for each 20 s interval. Each pair was tested daily for three consecutive days. Agonistic acts recorded consisted of tail rattling, wrestling, flank biting, chasing or full attack⁷⁻⁹. Any aggressive act by one mouse during a 20-s interval was scored as '1'; if both mice reacted aggressively during the same period, it was scored '2'. Aggression scores were obtained by summing the pair scores over the three trials and averaging these scores for each genotype.

† $\bar{X} \pm \text{s.e.m.}$; maximum possible aggression score was 180 for both studies.

‡ Number of male pairs tested.

§ Neuman-Keuls analysis of aggression score means; $P < 0.05$ (after Winer¹⁰).

¶ Underlined means are statistically equivalent.

Table 2 Matherian scaling of aggression scores

Table 1 indicates the aggression score obtained in the two experiments. The scores for each parental strain and thus for the mid-parental values are essentially unchanged. In the initial study, a marked but non-significant difference ($P < 0.10$) was noted between the two reciprocal F_1 mice. This difference attained significance in the replication ($P < 0.05$; Student's t test). Analysis of variance for all four genotypes indicates a highly significant F statistic for both samples ($P < 0.001$). A Neuman-Keuls analysis designates the significant differences between genotypes (Table 1). In the initial study, the score of the B10D1F₁ is similar to that of the DBA/1 strain; whereas in the replication, it is closer to that of the mid-parent. In the same study, the score of the D1B10F₁ is similar to that of the mid-parental value; whereas in the replication, it is closer to that of the C57BL/10/Bg strain. These relationships can be seen more clearly on a Matherian scale (Table 2) where the aggression score of each genotype is represented as a deviation from the mid-parental value¹⁰. In both samples, the reciprocal differences are in the same direction, and their magnitude, measured as deviations from the mid-parental values, are essentially the same.

A possible autosomal contribution to aggressive behaviour was detected in the original study⁶, in a study by Eleftheriou *et al.*¹¹; but not in the present one. The factors accounting for this discrepancy are possibly that the animals used in the replication, though of the same substrain (Bg), were at least 20 generations removed from those used in the initial study. They were also maintained under specific pathogen-free conditions, while the original animals were housed in a conventional colony. That the Y chromosomal contribution could be replicated in the hands of a second investigator under somewhat different environmental and testing conditions suggests that the latter effect is more robust.

Since the DBA/1/Bg mice are more aggressive than the C57BL/10/Bg mice, and since the magnitude of the F_1 scores is associated with that of the male parent, it is a reasonable hypothesis that the reciprocal differences in aggressiveness are the result of the reciprocal differences in the origin of the Y chromosome, as previously suggested¹². Because the more aggressive hybrids developed in the uterine and postnatal environment of the less aggressive C57BL/10/Bg strain, these maternal conditions seem to make no major contribution to the aggressive behaviour of these strains and hybrids.

Although there seems to be an incremental effect of the Y chromosome derived from DBA/1/Bg mice on aggressive behaviour, our studies indicate that the Y chromosome of the aggressive DBA/2/Bg strain does not potentiate intermale fighting when analysed in similar crosses. Also, in reciprocal crosses between CFW and A/J mice, Southwick¹³ reported that F_1 mice sired by the more aggressive strain (CFW) were not more aggressive than their reciprocal F_1 generation. Thus, the variation in intermale fighting in mice is very likely under the control of a variety of genetic factors, including the Y chromosome.

These results add to the growing evidence¹⁴⁻¹⁷ which suggests

that the Y chromosome, in at least one mammalian species, is not inert and that extrapolating from mouse to man, there may be active genes on the Y for traits other than hairy ears, foot ulcers and radio-ulnar synostosis¹⁸. Our hypothesis thus places constraints on inferring behavioural potential from the XYY karyotype of man or other mammals.

Response of flying mole crickets to three parameters of synthetic songs broadcast outdoors

LARGE numbers of flying crickets can be attracted to outdoor loudspeakers broadcasting male calling songs¹. Consequently we have been able to investigate the features of calling songs that are important for attraction. Previous investigators have used laboratory-maintained crickets in acoustical environments significantly different from outdoors²⁻⁷. Furthermore, they have studied thoroughly no more than one or two of the important signal parameters. We have studied outdoors the responses of free-flying mole crickets, *Scapteriscus acletus*, to synthetic call-

ing songs systematically varied in these three parameters: carrier frequency, pulse rate and intensity. Mole crickets came in greatest numbers when we broadcast, at unnaturally high intensities, carrier frequencies and pulse rates like those of the natural song.

All experiments were conducted near Gainesville, Florida, during 1972 and 1973. During the tests soil temperatures were $24 \pm 4^\circ \text{C}$, air temperatures, $25 \pm 5^\circ \text{C}$, and relative humidity, $70 \pm 20\%$ (ref. 8). We used three independent broadcasting systems, each with its own cricket-trapping funnel. A fourth funnel, without a speaker, was the control. Two test sounds and a standard sound were broadcast simultaneously. Test sounds were synthetic songs (artificial sounds synthesised and tape-recorded in the laboratory) varied in intensity, carrier frequency and pulse rate (that is, rate at which the carrier was turned on and off). Equal durations of pulses and pulse intervals were maintained. For frequency experiments (1972), the pulse rate and intensity were held constant at 60 pulses s^{-1} and 100 dB sound pressure level (SPL) (at 15 cm; reference SPL, $2 \times 10^{-5} \text{ N m}^{-2}$). Similarly, in pulse rate experiments (1973), the frequency and intensity were held constant at 2.7 kHz and 100 dB. In intensity experiments (1973), frequency and pulse rate were constant at 2.7 kHz and 55 pulses s^{-1} . The standard sound was 2.7 kHz and 100 dB. It was changed from 60 pulses s^{-1} in 1972 to 55 pulses s^{-1} in 1973 to approximate more closely the natural song (that is, the actual calling song of males in the field) at 25°C . The number of mole crickets trapped at each test sound was expressed as a percentage of the number caught at the standard sound. Trials with less than 10 crickets in the standard were discarded. Each test sound was used on at least two nights. We have described the trapping equipment and the broadcasting techniques before¹.

The control funnel generally caught no mole crickets and never had more than 1.5% of the number of adults in the other three funnels. In frequency and pulse rate trials the number of trapped mole crickets varied fivefold about a mode (Fig. 1). For every 6-dB increase in sound level up to 106 dB, our catch approximately doubled (Fig. 2). In addition to comparing seven pulse rates, we investigated whether any amplitude modulation at all was necessary for phonotaxis of *S. acletus*¹⁰. We made four trials comparing a continuous tone (no amplitude modulation) of 2.7 kHz with the 1973 standard sound (tone turned on and off 55 times per second). Because 270 *S. acletus* were captured at the standard sound, 27 at the continuous tone, and none at the control, amplitude modulation must be an important, but not essential, feature.

Several features of male calling songs are known or suspected to cause species-specific responses in crickets²⁻⁷. For mole crickets, Bennet-Clark¹¹ suggested that carrier frequency might

Fig. 1 The response of flying *S. acletus* to synthetic sounds that were systematically varied in frequency (a) and pulse rate (b). The relative response is a percentage of those captured at the standard sound (circle and cross) (see text). Vertical bar is 2 s.e. on either side of the mean. Narrow vertical line is range. In 16 frequency trials, 416 individuals were trapped; in 24 pulse rate trials, 843 were trapped.

Fig. 2 The response of flying *S. acletus* to various intensities. Relative response is a percentage of those captured at the standard level (circle and cross, 100 dB). (●) Represents result of a single trial with a different speaker. The dotted line represents a doubling of the number for each 6 dB increase in sound pressure level. Vertical bar is 2 s.e. on either side of mean. Narrow vertical line is range. In 33 intensity trials, 1,606 individuals were captured.

be important to flying females. Our data (Figs 1 and 2) demonstrate that both carrier frequency and pulse are important to species-specific phonotaxis in *S. acletus*. This insect (Orthoptera, Gryllotalpidae) should be able to separate its own song from songs of most other crickets by pulse rate (Fig. 1); however, there are crickets occurring in the same habitat with pulse rates overlapping those of *S. acletus*. *S. acletus* could distinguish the songs of its own males from the songs of these other crickets by carrier frequency, since carrier frequency of these songs is higher than in *S. acletus*¹.

Doubling of catch for each 6-dB increase in sound level agrees with the following model. Sound waves radiate in all directions from loudspeakers, and sound pressure is generally halved (that is, drops 6 dB) for each doubling of distance from a sound source. Whatever the shape of the sound field, its diameter would double for each 6-dB increase in sound level. To orientate to a calling song, the flying adults must first encounter an appropriate sound above a threshold pressure. If mole crickets fly in a single plane and maintain straight courses, the catch should double for each doubling of diameter (not the area) of the sound field. The failure of doubling to continue with each increase of 6 dB beyond 106 dB could result from the crickets being repelled by such high intensities or from an inability to orientate owing to saturation of their auditory organs.

The synthetic songs that trapped maximal numbers of mole crickets had pulse rates and frequencies like those of the natural song but the catch was increased 30-fold at intensities 38 dB or more above natural intensities, which average 68 dB⁹. Such attraction may prove useful in control of these agricultural and turf pests.

We thank Dr J. E. Lloyd and Mr D. L. Mays for criticising our manuscript.

Ripening of tomato fruits at reduced atmospheric and partial oxygen pressures

STORAGE at reduced atmospheric pressure and low temperature is used to retard the post-harvest senescence of fruits, vegetables, cut flowers, and cuttings¹⁻³. The effect of this low pressure storage (LPS) has mainly been ascribed to reduction of the internal concentration of the senescence-accelerating gas ethylene⁴, although occasionally effects of a lowered partial oxygen tension (P_{O_2}) have also been reported⁵⁻⁷. To determine the contribution of the reduction in P_{O_2} to the total effect of LPS on the retardation of post-harvest senescence, we studied the course of ripening of tomato fruits at different atmospheric and partial oxygen pressures, with and without absorbing the ethylene produced. We report that both the onset and the rate of the ripening process are determined by the oxygen pressure, irrespective of the atmospheric pressure and the absorption of endogenously evolved ethylene.

Tomato fruits of the Jupiter cultivar were grown under greenhouse conditions and carefully selected from the same position at comparable clusters. Samples of 15 mature green fruits were placed in 21-l desiccators over dry lime to absorb the carbon dioxide produced. Part of the desiccators also contained a 3% potassium permanganate solution in 1 N sulphuric acid, to absorb the ethylene evolved. The ethylene concentration in the desiccators was measured daily using a gas chromatograph. After gas sampling the desiccators were flushed to refresh the atmosphere completely. Gas mixtures were applied from cylinders and the atmospheric pressure adjusted by suction. When the fruits were in their climacteric stage, respiratory oxygen consumption never reduced P_{O_2} below 0.18 and 0.037 at initial P_{O_2} values of 0.21 and 0.04, respectively. The respiration rate at $P_{O_2} = 0.1$ was still equal to that at $P_{O_2} = 0.2$, but at a pressure of 4% it must be considerably reduced. The onset and rate of ripening were followed daily using visual colour determination, and at the table-ripe stage the softness of the fruits was also measured⁸. The weight loss never exceeded 2%. Table 1 summarises the results of an experiment at 19° C, under diffuse light from fluorescent tubes.

The normal period taken to ripen, 7 days, is delayed by pure oxygen at $P_{O_2} = 1.0$; also the lycopene synthesis is disturbed, the ripe soft fruits becoming intensely orange but not red. At about $P_{O_2} = 0.2$, however, the presence of other atmospheric components fails to affect ripening, the fruits ripening in 7 days both at normal and at reduced atmospheric pressure, whether or not the ethylene is absorbed. Even at 19 cm Hg and in the presence of permanganate solution, the ethylene level does not limit the rate of ripening, whereas at the reduced oxygen level of 5%, ripening is considerably retarded, even without absorption of ethylene.

Table 2 shows an experiment at two temperatures, 19° C and 13° C. Again, at the normal P_{O_2} of 0.2 the usual ripening periods of 9 and 17 days occur at 19° C and 13° C, respectively,

Table 1 Rate of ripening of Jupiter tomato fruits, from the mature green to the table-ripe stage, at different atmospheric conditions at 19° C

Pressure (cm Hg)	Atmosphere	P_{O_2}	KMnO ₄	Days to ripeness
76	O ₂	1.0	+	13
			—	13
76	Air	0.21	+	7
			—	7

			—	29	32

regardless of the total atmospheric pressure and the absorption of ethylene. In the presence of permanganate solution, the level of ethylene never exceeded $2 \mu\text{l l}^{-1}$ and was usually much less than $1 \mu\text{l l}^{-1}$. Without ethylene absorption, the ethylene level at 20% oxygen surpassed the threshold value (ref. 9 $5 \mu\text{l l}^{-1}$) for ripening of tomato fruit within 2 days; at the reduced oxygen level of 4%, on the other hand, the ethylene level always remained below $4 \mu\text{l l}^{-1}$, mostly below $2 \mu\text{l l}^{-1}$, and the ripening was considerably retarded in all cases. The lack of oxygen is the overriding factor at $P_{O_2} = 0.04$, determining the rate of ripening. At normal atmospheric pressure the ripening was even more delayed than at reduced pressure.

That not only the rate, but also the onset, of ripening is delayed at a low partial oxygen pressure is shown in an experiment with earlier harvested fruits (Table 3). In air at normal pressure, the fruits started ripening after 4 days and reached the pink stage in 8 days. The reduced partial oxygen pressure of 4% postponed the onset of ripening considerably, again at an atmospheric pressure of 76 cm more than at 15 cm. The conclusion that oxygen is the limiting factor at this concentration, rather than ethylene, is supported by the fact that the presence of the permanganate solution is irrelevant.

Table 3 Delay of onset of ripening, to the first sign of colour breaking (stage 2), at different atmospheric conditions at 19° C

cm Hg	Atmosphere	P_{O_2}	KMnO ₄	Days to stage 2
76	Air	0.2	+	4
			—	4
76	N ₂ +O ₂	0.04	+	16
			—	16
15	Air	0.04	+	10
			—	13

We have therefore confirmed the usefulness of LPS in delaying post-harvest senescence. Contrary to earlier indications¹, however, we have clearly demonstrated that, at least for the commodity and conditions used, the effect of LPS is not primarily caused by a reduced ethylene concentration, but rather by the low partial oxygen pressure. In this respect LPS acts in a similar way to the well established method of controlled atmosphere storage, in which senescence is retarded by storage in an atmosphere reduced in oxygen and enriched in carbon dioxide by the respiratory activity of the commodity¹⁰⁻¹². Among the advantages of LPS are the more readily established atmospheric conditions and the continuous removal of carbon dioxide and ethylene. The reduced oxygen pressure may affect the onset and rate of ripening by inhibiting the biosynthesis or activity of ethylene^{12,13}, or by limiting the respiratory activity or interfering with the oxidation of, for example, indoleacetic acid¹⁴.

We also conclude that the concentration of endogenously evolved ethylene in the atmosphere has no effect on the onset and the rate of ripening, if it is not allowed to accumulate excessively. The ethylene produced in ripening tissue may well exert its physiological effect mainly during its passage, within the cell, from the site of biosynthesis to the intercellular space. The concentration of endogenous ethylene in the intercellular space is thus an indicator rather than an effector of ripening

and its reduction by low atmospheric pressure or absorption is not effective in regulating senescence.

Blue-green algae associated with ascidians of the Great Barrier Reef

In the rich biota of reef communities, one of the best known symbiotic relationships is that of dinoflagellates known as "zooxanthellae" with corals and giant clams^{1–3}. In contrast, the presence of algae in ascidians (sea squirts: Phylum Chordata, Subphylum Tunicata), although known for many years, has been studied very little. It is known that the association is confined to tropical ascidians in the family Didemnidae, but even the phylum to which the algae belong, or indeed whether the green cells in question are algae at all, has remained uncertain. During a recent expedition of the RV Alpha Helix to the Great Barrier Reef, we encountered several species of colonial ascidians containing large numbers of bright green, spherical cells. We have established by optical and electron microscopy that these green cells are blue-green algae; their association with primitive chordates represents a considerable extension of the known host range of these prokaryotes.

Our collections were made between March 25 and May 13, 1973, on reefs surrounding Lizard, Nymph and Turtle Islands off the north-east coast of Queensland (14°40'S, 145°30'E). Of the species of ascidians we collected five belong to the Didemnidae (Patricia Kott Mather, personal communication). We found that three of these [*Didemnum ternatanum* (Gottsch.), *Diplosoma virens* (Hartmeyer), and *Lissoclinum molle* (Herdman)] contained large numbers of algae. *Didemnum ternatanum* is a brown-coated, usually urn-shaped species 1–3 cm in height, while *Diplosoma virens* and *Lissoclinum molle* are blue and green encrusting forms, respectively. In all three ascidians the seawater strained of its plankton by the zooids collects in the labyrinthine central cloacal cavity of the colony, from which it is expelled through common excurrent pores. The algae are located extracellularly within cloacal pockets and folds around the zooids, or appressed to strands of the cellulose-like matrix or test that span the cloacal cavity (Fig. 1).

Earlier observations on the algae of didemnid ascidians had identified them as either zooxanthellae^{4,5} or zoochlorellae⁶, the latter category including various green algae associated with animals⁷. We concluded from light microscopy, however, that the algae in our ascidians are blue-greens, since they lack discernible nuclei and form new cells by wall ingrowth and constriction. These algae are bright green, their absorption spectra indicating the presence of chlorophyll *a* and little or no phycocyanin and phycoerythrins (T. Akazawa, personal communication). All three algae are unicellular and spherical, but in other respects differ sufficiently to be readily distin-

Fig. 1 Thin section through a coccoid blue-green alga lying in the cloacal cavity of the colonial tunicate *Diplosoma virens*. This electron micrograph illustrates the concentric lamellae, polyhedral inclusions and clear central area of the alga. The alga resides in a pocket formed by the test of the colony. Cells of a zooid can be seen at top right. Bacteria are embedded among the cellulosic fibrils of the test at lower left and elsewhere. Scale bar, 2 μ m.

guishable from one another. The algae of *Diplosoma virens* and *Lissoclinum molle* usually contain a clear central region not seen in the algae of *Didemnum ternatanum*. Also, the algae of *D. virens* range in diameter from 7–15 μ m whereas the algae from *D. ternatanum* and *L. molle* average about 20 μ m.

The three algae have a basically similar ultrastructural organisation but differ in detail. The cells lack mitochondria and other eukaryotic organelles, and their fine structural features are characteristic of blue-green algae (Figs 2 and 3a). Since the fine structural features are quite constant between algae from different collections of the same species of ascidian, a single micrograph is usually sufficient to enable identification of the alga in terms of its ascidian host (compare Figs 2 and 3b). On the basis of classical taxonomic features determined with the optical microscope, the algae from formalin-preserved colonies of all three ascidians have been identified as the single blue-green species, *Anacystis aeruginosa* (Zanard.) Drouet & Daily (Francis Drouet, personal communication). But, the consistent fine structural differences suggest that the three algae may represent different species, each associated with its particular species of ascidian.

There are reports of the presence of algae-like cells in the cloacal cavities of colonial ascidians. Herdman⁸ in 1906 mentioned their presence in the cloacae of *Diplosoma virens* and *D. viride* (= *D. virens*) from Ceylon. On the Yonge expedition to the Great Barrier Reef in 1928–29, Hastings⁴ observed brownish algal inhabitants in the cloacal cavities of three didemnid ascidians, including *D. virens* and *Lissoclinum molle*. The algae were identified as zooxanthellae by Yonge⁴ whose identification was corroborated by Smith⁵ from preserved specimens. Smith also pointed out, however, that in a collection of *D. virens* from Ceylon the algae, being green, were possibly zoochlorellae. More recently, Tokioka⁶ examined ascidians from the Pacific Ocean in the United States National Museum and found that seven didemnids harboured algae, all of which were identified as zoochlorellae. Thus there are several didemnid

Fig. 2 Ingrowth of the wall bounded by the plasmalemma during cell division by constriction in the alga from a mature colony of *Didemnum ternatanum*. The osmiophilic globules are characteristic of the algae in this ascidian. Scale bar, 0.4 μ m.

ascidians in which zooxanthellae and zoochlorellae have been reported from different collections of the same species.

We conclude from our observations that some or all of the zoochlorellae reported in ascidians by past workers may have been blue-green algae. In any event it seems clear that in several cases a particular ascidian species is capable of harbouring either of two quite different algae. Thus *Diplosoma virens* and *Lissoclinum molle* collected at Low Isles on the Yonge Expedition contained zooxanthellae, while the same species collected by us approximately 115 miles north of Low Isles (and 45 years later!) contained blue-green algae. There is no evidence that mixtures of the two kinds of algae occur. In examining thousands of algae and the tissues of many zooids in our didemnid ascidians, we have not found a single zooxanthella, although zooxanthellae exist in enormous numbers in the nearby corals and clams.

Although earlier reports have established the presence of either zooxanthellae or zoochlorellae in different collections of *Trididemnum cyclops*⁴⁻⁶, the presence of algae may not be necessary for the existence of this ascidian at least, as we found flourishing colonies of this species growing without algae on the underside of a coral rock. Whether the ascidians utilise photo-

synthetic products of the algae, as do clams and corals, has not yet been established. Tests for nitrogen fixation by the algae were negative (R. H. Burris, personal communication).

Previously, blue-green algae in the marine environment have been identified as symbionts only of certain diatoms¹⁻³ and a very few marine invertebrates, among which are certain sponges⁹⁻¹². The association we observed is therefore of special interest since it greatly extends the host range of blue-green algae to include primitive members of the Chordata, and thus represents an association with marine animals considerably higher in the evolutionary scale than hitherto recognised.

Our formalin-preserved ascidians have been deposited in the Queensland Museum; we thank Dr Patricia Kott Mather for their identification. We also thank Mr J. E. Burris and Drs T. Akazawa, J. S. Bunt, R. H. Burris, I. R. Price and D. D. Randall for assistance in collecting, and Dr L. Muscatine for advice. This work was supported by grants from the National Science Foundation to the Scripps Institution of Oceanography for operation of the Alpha Helix Research Program, and by a grant from the National Science Foundation to the senior author.

Heteroantagonism observed in mixed algal cultures

RUSSELL¹ has referred to the curious lack of interest shown by marine ecologists in species competition, especially in view of the suitability of existing cultural techniques for investigating this problem. Certainly much more experimental work using mixed cultures has been carried out by examining competition in planktonic algae²⁻⁷ than in benthic algae⁸. This is perhaps surprising in view of the wealth of information, particularly that derived from studies on the algal colonisation of cleared or new substrata, which suggests that competition factors also play active roles in benthic community structuring and may even, as deduced by Den Hartog⁹, influence zonation. Particularly interesting in this respect are the growing number of reports¹⁰⁻¹⁴ that polyphenols ('tannins') are actively liberated from the surfaces of brown algae, and that these compounds possess both antibacterial and antialgal properties¹⁵⁻²⁰. Indeed, the fucosan-vesicles or physodes commonly found in brown algal cells have been attributed the function of polyphenol storage²¹⁻²³. Although the antifouling properties of these secretions have been recognised^{7,16,17,19,20}, very little is known of their ecological influence beyond the surface of the host. Here I report on some observations of mixed cultures of the brown crustose alga *Ralfsia spongiocarpa* Batt. and the two crustose red algae *Porphyrodiscus simulans* Batt. and *Rhodophysema elegans* (Crouan frat. ex J. Ag.) Dixon.

Both the *Ralfsia* thalli and the two crustose red algae were collected from the rocky sides of low-tide-level pools at Peveril Port, Swanage, Dorset; laboratory cultures were established using unispores²⁴ and tetraspores, respectively. The abundance

Fig. 1 a, Part of a 6-week-old cultured crust of *Rhodophysemma elegans* showing inhibition of horizontal growth on the side adjacent to a knot-filament of *Ralfsia spongiocarpa* ($\times 64$). b, Closeup of (a) ($\times 136$).

of the *Ralfsia* under the field conditions²⁵ suggested that the thalli had competitive advantages. Cultured crusts of the two red algae were later 'seeded' around their perimeter with small portions of cultured *Ralfsia* 'knot-filament' thalli (for a description of this phase in the life history see ref. 25). Care was taken to ensure that the *Ralfsia* thalli did not come into contact with the crusts but were allowed to form a weak attachment to the floor of the Petri dish a short distance away from them. 'Control' cultures were also set up in which an approximately equal amount of red algal 'knot-filament' growth was placed adjacent to cultured crusts of the same species. All cultures were placed at 10°C, 8–16-h day conditions using Gro-lux fluorescent tubes at

Fig. 2 Part of a 4-month-old cultured crust of *Porphyrodiscus simulans* showing inhibition of horizontal growth on the side adjacent to a knot-filament of *Ralfsia spongiocarpa* ($\times 45$).

an intensity of 1,000 lx. The culture medium was replenished each week.

Within approximately 10–14 d the growth of the two red algal crusts was markedly inhibited on the sides adjacent to the *Ralfsia* thalli (Figs 1 and 2). The broad monostromatic zone, typically produced in the other regions of the germlings and in the control cultures by outer, actively dividing meristematic cells, was absent and polystromatic crust formation was evident right up to the thallus margin (Fig. 3).

Fig. 3 a, Surface view of normal, actively growing margin of a cultured crust of *Porphyrodiscus simulans* ($\times 201$). b, Surface view of the margin of the same crust adjacent to the *Ralfsia* thalli ($\times 173$).

In view of the rapid nature of the response, it is unlikely that this growth inhibition effect was caused by differential nutrient uptake by the two adjoining algae. The evidence strongly suggests that an antibiotic, which inhibits the growth of the two red algae, is secreted into the culture medium by the *Ralfsia* thalli. Certainly, reports on the production of antibiotics in this genus are not new: Conover and Sieburth²⁶ reported that tannins secreted from *Ralfsia verrucosa* (Aresch.) J. Ag. in tidepools may be suppressing barnacle and mussel colonisation.

The possible involvement of antibiotics as controlling factors in crustose algal formations adds a new dimension to existing interpretations based predominantly on differential growth rates and/or selective grazer activity. It also bears important implications for the growth of erect thalloid species, the success of which will depend on the establishment and sustained growth of the basal attachment systems.

I thank Mrs L. M. Irvine (British Museum (Natural History)) for help and encouragement.

Possible location of chlorophyll within chloroplast membranes

THE inner membranes of the chloroplasts of higher plants and green algae contain the photosynthetic apparatus for the conversion of solar energy to chemical energy¹. Light is absorbed primarily by the chlorophylls, most of which act in a light-collecting capacity to absorb and transfer energy to the reaction centre chlorophylls of the two photosystems where the primary quantum conversion takes place². The chlorophylls comprise about 10% of the mass of mature chloroplast membranes or 20% of the total lipid mass. Because of their key role in photosynthesis, a question of prime importance is the location of the chlorophylls in chloroplast membranes. Earlier proposals have been reviewed by Kreutz³.

A plausible model for membrane structure is the fluid lipid-protein mosaic where the membrane continuum consists of a lipid bilayer in which intrinsic proteins are embedded and to which extrinsic proteins are attached. Although intrinsic proteins may be highly hydrophobic they are amphipathic molecules with a hydrophilic region located at the membrane surface; in some cases the molecule may extend through the membrane and have two hydrophilic regions, one at each surface of the membrane⁴⁻⁷. There also seem to be two classes of lipids: fluid, mobile lipids which make up the matrix of the lipid domain; and fixed, boundary lipids, which consist of monomolecular layers attached to the hydrophobic shells of the penetrating intrinsic proteins^{8,9}.

Assuming the lipid-protein mosaic model to be valid for chloroplast membranes, the following reasons suggest that the bulk of the amphipathic chlorophyll molecules would be boundary lipids. If chlorophylls were located in the fluid lipid domain, the molecules would be free to move laterally in a random fashion through the membrane and the specific arrangement of the porphyrin rings essential for energy transfer would be impossible. This difficulty would not arise if the porphyrins were located in the protein region where ordered arrangement would be feasible. Indeed, it is likely that chlorophyll is attached to protein because two chlorophyll-protein complexes have been isolated from chloroplast membranes, following their solubilisation with sodium dodecyl sulphate. These two complexes make up some 70% of the intrinsic protein mass of mature chloroplast membranes: chlorophyll-protein complex 1, associated with photosystem 1, comprising some 20% and chlorophyll-protein complex 2, associated with photosystem 2, some 50% of the intrinsic protein^{10,11}. Moreover, it seems likely that most of the chlorophyll is attached to these complexes *in vivo*.

As well as porphyrin-protein interaction, the phytol chains would be associated with the hydrophobic regions of the two major intrinsic proteins. In a detailed molecular model proposed for chloroplast membranes, Weier and Benson¹² placed phytol chains, together with the acyl chains of the other chloroplast membrane lipids, into the hydrophobic interiors of lipoprotein subunits. Although this model¹³, in which the membrane is composed entirely of a sheet of lipoprotein subunits, is no longer considered feasible¹⁴, it is possible to consider that the phytol chains will reside exclusively within the hydrophobic regions of the intrinsic proteins of the lipid-protein mosaic membrane. Alternatively, I propose that phytol could be associated with the hydrophobic exterior of the intrinsic proteins and thus chlorophyll would be part of the boundary lipids of the two chlorophyll-protein complexes. Less energy would be required to attach the phytol chains to the protein exterior than to bury them completely in the hydrophobic protein

Fig. 1 Chlorophyll α .

interior. Further, anchoring the phytol chains at the protein exterior ensures that they will be perpendicular to the plane of the membrane and allows the porphyrin rings to be tilted with respect to the membrane surface.

Physical measurements indicate that the porphyrins are orientated at an angle of 48° to the membrane surface¹⁵. This orientation is analogous to that observed when chlorophyll is artificially incorporated into bilayers¹⁶⁻¹⁸. One edge of the square planar tetrapyrrole macrocycle, adjacent to phytol, is hydrophilic since it includes the cyclopentanone ring V and the carbonyl group of the propionic side chain of ring IV, to which phytol is attached; the Mg^{2+} also has hydrophilic properties (Fig. 1). This hydrophilic edge would interact at the aqueous membrane surface with the hydrophilic region of the intrinsic protein giving the porphyrin

ring the required tilt; the more hydrophobic portion of porphyrin would thus extend further into the hydrophobic protein region of the membrane. A schematic diagram is shown in Fig. 2 with chlorophyll molecules surrounding an intrinsic protein; additional lipids would be required to complete the boundary lipid monolayer. The necessary but undefined aggregations of the porphyrins would be possible in this model, and it would be expected in such arrays that the chlorophyll molecules will occur in several environments arising from interactions with other chlorophyll molecules, thus giving rise to the complexity of the *in vivo* spectra^{19,20}.

An additional reason for placing the light-harvesting chlorophylls as boundary lipids is evident when one considers the lipid content of chloroplast membranes. If intrinsic proteins are to be covered with boundary lipids as much as 35% of the total lipid molecules of chloroplast membranes may need to be immobilised. At least 30% of the total lipid mass consists of functional lipids, such as the chlorophylls, carotenoids and plastoquinones, which are not involved in formation of the bilayer. Obviously it is advantageous to use the chlorophylls, and probably also some carotenoids, as boundary lipids in order to leave sufficient lipids to form the fluid matrix.

Fig. 2 Schematic cross section of a chloroplast membrane showing an intrinsic protein spanning the membrane, with hydrophilic regions located at the membrane surfaces and a hydrophobic portion (shaded) embedded within the nonpolar interior of the lipid bilayer. The chlorophyll molecules (shown on the left, with the hydrophobic portion of the porphyrin ring shaded) are part of the boundary lipid of a chlorophyll-protein complex. The phytol chains are perpendicular to the membrane surface in close interaction with the outside perimeter of the hydrophobic region of the intrinsic protein, and thus in contact on one side with protein and on the other side, with the acyl chains of the fluid lipid matrix. In contrast, the porphyrin rings are buried within the protein; the hydrophilic edge of the porphyrin ring is located at the membrane surface and the hydrophobic part is buried within the hydrophobic interior of the intrinsic complex.

If the chlorophylls are boundary lipids of the two major chloroplast intrinsic proteins as postulated, the porphyrins would be located towards the external or internal surface of the membrane. It is unlikely that the chlorophylls of an individual pigment complex would be divided between the outer and inner surfaces since this would markedly decrease the efficiency of light trapping. Briantais *et al.*²¹ favour the view that the porphyrin rings of the two photosystems are located on opposite sides of the membrane, with photosystem I at the external surface. On the other hand, Radunz²², using an antiserum monospecific to chlorophyll α , showed that part of the chlorophyll α of both photosystems was accessible to antibodies. Thus, a definitive answer to the question is not yet available. An important consequence, however, of chlorophyll being a boundary lipid is that the chlorophyll molecules will not be uniformly distributed over the membrane; rather they will occur only where the intrinsic proteins are located.

I am very grateful for discussions with Dr D. S. Bendall, and for tenure of the Ann Horton Research Fellowship at Newnham College.

Prostaglandins as haemostatic agents

It has been reported that prostaglandin endoperoxides (PGG₂ and PGH₂), possible intermediates in the biosynthesis of PGE₂ and PGF_{2α} from arachidonic acid, may be mediators of platelet aggregation¹⁻³. Kloeze reported⁴ that neither PGE₂ nor PGF_{2α} cause platelet aggregation or ADP release, and Willis⁵ stated that prostaglandins themselves cannot induce platelet aggregation. But we have found that three synthetic prostaglandins, Wy-16, 991, Wy-17, 185 and Wy-17, 186, induce platelet aggregation *in vitro*, and two of them, Wy-17, 185 and Wy-17, 186, significantly shorten the Lee White clotting time in rats. The most active of the three, Wy-17, 186, exerts a haemostatic effect on a bleeding wound surface.

Table 1 Effect of prostaglandins on Lee White clotting time of fasted male rats

Compound	Dose ($\mu\text{g kg}^{-1}$)	No. of rats	Mean Lee White clotting time (s \pm standard error)		5 min
			1 min	No. of rats	
Control	—	8	341.2 \pm 13.1	7	340.7 \pm 13.6
Wy-17, 186	250	11	330.0 \pm 22.9	9	296.7 \pm 18.5
			NS		NS
Control	—	9	378.3 \pm 12.4	8	356.3 \pm 25.1
Wy-17, 186	500	9	281.7 \pm 12.4	7	242.1 \pm 24.9
			$P < 0.01$		$P < 0.01$
Control	—	9	393 \pm 10.9	8	401 \pm 8.4
Wy-17, 18	500	11	358 \pm 10.9	8	363 \pm 9.0
			$P < 0.05$		$P < 0.05$
Control	—	10	405.0 \pm 21.1	8	373.1 \pm 24.9

			NS		NS
Control	—	8	433.1 \pm 9.8	5	435.0 \pm 9.2
Wy-16, 991	500	8	405.0 \pm 12.5	6	412.5 \pm 16.3
			NS		NS

Human blood was collected in siliconised 50 ml Vacutainers (Becton and Dickinson) fitted with siliconised 18 gauge needles using 3.8% sodium citrate as the anticoagulant (9 parts of blood to 1 part of sodium citrate). Platelet-rich plasma (PRP) was separated from the red blood cells and the effect of the prostaglandins on platelet aggregation was studied with a Payton Aggregation Module as described previously⁶.

To test the effect of these compounds on blood coagulability, groups of ether-anaesthetised male rats were given intravenous injections of the prostaglandin in physiological saline or saline control solution. Blood was obtained by cardiac puncture for the determination of the Lee White whole blood clotting time either 1 or 5 min after injection.

The haemostatic activity at a bleeding wound surface was determined by either exposing the femoral vein of Nembutal-anaesthetised rats and making a standardised nick (1–2 mm) in the vein with a lancet, to yield a free flow of blood, or opening the abdominal cavity to expose the mesenteric matrix of small blood vessels and making a 1–2-cm cut across these vessels with a scalpel. A 200 or 400 $\mu\text{g ml}^{-1}$ solution of the prostaglandin in physiological saline, or plain saline, was dripped on to the bleeding surface at a rate of about 1 drop per 5 s, and the time required for the cessation of bleeding was measured. The prostaglandins used were synthesised by Drs D. Strike and W. Kao.

A typical plot of the platelet aggregation induced in human PRP by these prostaglandins (3 $\mu\text{g ml}^{-1}$) compared with that induced by ADP (Fig. 1) shows them to be slightly less active

than ADP. Maximal platelet aggregating activities of Wy-17, 185 and Wy-17, 186 at 26 μM are inhibited 50% by 0.033 μM and 0.092 μM PGE₁, respectively. It is interesting that the aggregating activity of these prostaglandins can be inhibited by another prostaglandin, PGE₁.

Table 1 shows the effects of the prostaglandins on the Lee White clotting time. In a dose of 500 $\mu\text{g kg}^{-1}$ Wy-17, 185 and Wy-17, 186 had a significant effect both 1 and 5 min after injection. Since the reduction by Wy-17, 186 was somewhat greater, it was tested for haemostatic activity *in vivo*.

When Wy-17, 186 was dripped on to the wound surface of the femoral vein of 10 rats at a concentration of 200 $\mu\text{g ml}^{-1}$, the bleeding time was 77.8 \pm 5.6 s compared with 97.4 \pm 6.2 s for 10 controls. This bleeding time reduction was significant ($P < 0.05$). When a 400 $\mu\text{g ml}^{-1}$ concentration of Wy-17, 186 was instilled over the bleeding mesenteric vascular bed, the bleeding time for seven rats was 174 \pm 16.9 s, compared with 395 \pm 25 s for six controls. This reduction in bleeding time was significant ($P < 0.001$).

Apart from the endoperoxides, the activity of the stable prostaglandins reported here represents a unique example of prostaglandins capable of inducing platelet aggregation. Furthermore, Wy-17, 185 and Wy-17, 186 can shorten the Lee White clotting time, and Wy-17, 186 significantly shortens the bleeding time from a wound surface. The control of bleeding from a wound surface is a first step in the healing process. A potential application of the activity of this haemostatic prostaglandin may be in the prevention of excessive postsurgical bleeding, or in helping to control oozing of blood from a wound surface during surgery.

'microcrystalline' and which is not easily detectable by DTA, becomes dissolved and leaves behind a coarser residue which gives a more pronounced DTA inversion peak.

Talbot⁶ states that under the abnormally severe conditions of prolonged dry grinding employed by Sakabe⁷, quartz can be converted to vitreous silica. Our evidence, however, does not support that idea.

The transformation of quartz to vitreous silica during grinding depends on whether conditions are such as to cause melting of the quartz. High temperatures and pressures during grinding are often vaguely discussed in terms of adiabatic compression, friction, electrical or other effects, but it seems⁸⁻¹⁰ that pressures of only a few tens of kilobars are produced during grinding.

Wackerle¹¹ demonstrated the conversion of quartz to vitreous silica using explosive driving systems to generate shock pressures in excess of 383 kbar. It seems unlikely that pressures of that magnitude would be produced during the process of grinding. Friction might produce temperatures of the order of 1,500°C (required to melt quartz) but only for very short periods because the average temperature of a mill during running is typically no more than 50°C; but the melting of quartz is quite slow¹² and it can be considerably overheated without melting if the temperature is rising rapidly. Thus, it seems that even under prolonged dry grinding, conditions cannot result in the transformation of quartz into vitreous silica.

Sakabe⁷ stressed the importance of the very small particles which adhere to the larger ones and he apparently never concluded that vitreous silica was produced from quartz during grinding.

One of the great difficulties of applying the concept of a 'Beilby layer' to the grinding of substances, was encountered by Clelland¹, who found that vitreous silica itself exhibited an initially high solubility when ground to a powder. The production of a skin of vitreous material over a material already vitreous does not explain satisfactorily an initial high solubility. The explanation seems to lie either in the formation of very small adherent particles, or grains within each particle, or perhaps more probably is caused by absorption of atmospheric moisture during grinding, resulting in hydrated layers. Both quartz and vitreous silica absorb atmospheric moisture during grinding¹³ and that effect seems to have been overlooked in relation to such properties as solubility characteristics or density of the powder; many researches either do not mention drying procedures, or else have used inadequate drying procedures which do not provide the temperatures of the order of 1,000°C required to liberate the combined water.

We conclude that quartz is converted during grinding into a microcrystalline form not readily detectable by differential thermal analysis. Processes such as sedimentation or etching in hydrofluoric acid, which result in the removal of the finest particles, leave behind coarser residues which behave more like the original quartz and give a more pronounced inversion on DTA curves.

Short-range order in crystals

DURING recent studies of computer-grown crystals evidence has come to light that could possibly account for an inconsistency which has hitherto existed in the interpretation of the X-ray diffraction patterns of some real crystals which contain short-range order.

It has become increasingly evident that many crystalline materials ranging from minerals to organic molecular crystals contain some kind of short-range order. In many the interatomic forces which give rise to short-range order (either at crystallisation or subsequently through the process of diffusion) are relatively long-range, but in organic molecular crystals the forces of interaction between molecular species are short-range van der Waals' forces typically acting over only a few Ångströms. In such cases it has seemed inconsistent when the short-range order as observed by X-ray diffuse scattering apparently indicates interactions over much greater distances.

For example, during its phase transition acenaphthylene¹ assumes a structure tending to repeat every 42 Å along the *c* axis although the dimension of its unit cell at room temperatures is only 14 Å and the closely packed molecular layers are only 7 Å apart. One-dimensional models of crystal disorder^{2,3} suggest that to explain such a pseudo-tripling of the cell it is necessary to consider interactions between second and possibly third

Fig. 1 *a*, Sample array; *b*, optical diffraction pattern produced by this array.

nearest neighbouring cells, that is interactions in the range 30–40 Å.

But a two-dimensional model of crystal disorder has been developed³ and more recent studies of this model have shown that it is possible to produce a pseudo-tripling of a cell repeat in one direction when only nearest-neighbour interactions are involved.

The array shown in Fig. 1a is a small representative portion of a much larger array (500 × 500 lattice points) which was computer-grown with the model described in ref. 3. The occurrence of the two molecular species A (represented by a hole) and B (represented by a blank) at a particular lattice site is decided by consulting the nearest lattice point above and the nearest to the left. For a given combination of the species at these two lattice points (there are four: A^A, A^B, B^A, B^B) there is a constant probability that the lattice point in question is an A. In the particular example shown the probability that an A occurs after A^A is 0.0, the probability that an A occurs after B^B is 0.2, the probability that an A occurs after an A^B is 0.8, and the probability that an A occurs after B^A is 1.0.

The optical diffraction pattern of this array (Fig. 1b) has a peak in the diffuse diffraction profile at about 1/3 and 2/3 of the cell repeat indicating a tendency to a tripling of the repeat in the lattice of Fig. 1a, though this is not readily apparent simply by viewing the lattice. I emphasise that such a diffraction profile is not possible with a one-dimensional model of disorder if only nearest-neighbour interactions are involved.

It seems likely that, in real crystals where interactions in three dimensions must be considered, even more dramatic effects may be possible. Effects such as those shown by acenaphthylene may, therefore, not need the consideration of non-nearest-neighbour interactions: this possibility is being investigated by extending the present two-dimensional models to three dimensions.

Gynodioecy in an animal

GYNODIOECY, a breeding system in which the population consists of hermaphrodites and females only, is a well known botanical phenomenon with a literature dating back at least to Darwin¹. It has never previously been reported in an animal.

A population of the sea anemone *Epiactis prolifera* Verrill, 1869, living in the rocky intertidal zone near Bodega Marine Laboratory, Sonoma County, California, was studied from April 1970 to March 1972. Of 269 animals from monthly collections examined histologically, 31 were sterile, 138 were female, and 100 were hermaphroditic (Fig. 1). This pattern of gynodioecy persisted all year round. Fertile anemones ranged from 5.8 to 35.7 mm in basal diameter. As an effort was made to include individuals of all sizes in each collection, the largest and smallest animals were represented in excess of their relative proportions in the population.

E. prolifera broods its young externally, one of 16 actinian species known to do so². Females and hermaphrodites spawn relatively few large yolky eggs which soon adhere to the parent's ectoderm, where they develop directly into juvenile anemones. When sufficiently large, juveniles move from the parent on to the surrounding substrate (D.F.D., unpublished).

Some ideas from the botanical literature are relevant to an analysis of the breeding system of *E. prolifera*, but that part consisting of genetic analyses and models^{1,3–8} is not. Among gynodioecious plants which have been examined, individuals are genetically either hermaphroditic or female. In *E. prolifera* it seems that sex determination is virtually identical in all individuals so that animals begin their reproductive lives as females, and most that survive sufficiently long become hermaphrodites. Thus gynodioecy in *E. prolifera* is serial and developmental, whereas in plants it is fixed and genetic.

A major advantage of gynodioecy—its ability to adjust the degree of heterozygosity in a population^{3,4,9}—obtains only if the species is at least potentially self fertile. There is no reason to dismiss this possibility in *E. prolifera*, where ripe ova and spermatozoa frequently occur in the same animal simultaneously (D.F.D., unpublished). If hermaphroditic individuals were facultatively self fertile, advantageous characters, including those which enabled them to survive sufficiently long to develop testes, could be fixed in the genome of the population by homozygosity. Under favourable environmental conditions, longevity would increase, raising the proportion of hermaphrodites in the population and thereby the potential for inbreeding. When conditions were such that few anemones survived long enough to develop testes, inbreeding would decline, thus increasing the proportion of heterozygous offspring with greater genetic flexibility to meet the stressful conditions.

Genetic factors allowing animals to survive long enough to develop testes and producing gynodioecy in *E. prolifera* are favoured numerically, even if selfing is impossible. Offspring of females receive half their genes from hermaphrodites; those of hermaphrodites receive all of theirs from hermaphroditic parents, one if by selfing and two if by crossing. Thus the genetic contribution to the next generation from hermaphrodites, no matter how few, cannot be less than 50%. It is usually greater because hermaphrodites will have already produced offspring as females, and because larger anemones brood more young (D.F.D., unpublished).

It is crucial to the species' success that the prevalence of egg-producing individuals in the population be as great as possible, for fecundity of *E. prolifera* is restricted by brood space. The strategy of having barely enough males to fertilise the ova produced by a population consisting largely

Fig. 1 The relationship between size and gonadal state of 269 *E. prolifera* collected approximately monthly over a period of 2 yr. Size classes are based on pedal disk diameter at the time of collection.

Effects of temperature and pressure on short term storage of platelets

NONE of the methods suggested so far to improve the storage life of platelets has proved entirely satisfactory¹⁻⁵. Storage at 22°C is the most accepted method³, and other suggestions include the use of chemical additives such as prostaglandin E₁ (ref. 5) or freezing techniques⁷⁻⁹. Studies involving a controlled rate of freezing and thawing in the presence of dimethyl sulphoxide have been encouraging¹⁰⁻¹², but a better method is desirable as the need for platelets is increasing rapidly. An improved method of storage might be developed if the normal discoid shape could be maintained. Furthermore, if the change in shape that occurs when platelets are cooled is accompanied by an increase in volume, as has been suggested¹³⁻¹⁵, or if the strength of the bonds maintaining the secondary and tertiary structure of the protein of the platelets is affected significantly by temperature or pressure, the application of sufficient pressure might shift the equilibrium towards a conformation favouring the discoid form. We have now found that pressure (2,500–9,000 pound inch⁻²) (17.24–61.65 N m⁻²) prevents to a considerable degree these changes in shape, and restores the shape of platelets in concentrates that have been kept at 2°C and atmospheric pressure for 1–2 h.

We first monitored the changes in shape using a water-jacketed high pressure optical cell in a Cary 14 spectrophotometer and samples of human and bovine blood platelet-rich plasma and platelet concentrate when pressure and temperature were varied. (Human platelet concentrates, from the Community Blood Bank of Kansas City, were prepared by collecting 500 ml of whole blood in a Fenwall GA-35 transfer pack containing 70 ml of acid citrate dextrose solution. Samples were centrifuged at 3,000g for 3 min, and the supernatant platelet-rich plasma was centrifuged at 5,000g for 5 min. The platelets were then resuspended in about 30 ml of plasma.) When low temperature studies were conducted a stream of nitrogen was passed through the cell compartment to prevent water condensation. Cooling consistently caused an increase in the absorbance which was reversed when pressure was applied to the cooled sample. A typical

Fig. 1 Absorbance at 620 nm of a platelet concentrate diluted 1:2 with saline solution as a function of applied pressure. O, Absorbance values measured 5 min after application of the designated pressure; □, absorbance corrected for the effect of pressure at room temperature. The sample is ~24 h old.

Fig. 2 Electron micrographs of platelets showing: *a*, typical discoid profile at room temperature and 1 atm of pressure; *b*, the numerous pseudopodial extensions and rounded form at low (2°C) temperature and 1 atm pressure, and *c*, discoidal forms at low temperature accompanied by pressure. (*a-c*, $\times 13,400$). Micrographs at higher magnification of the margin of platelets show (*d*) the absence of the marginal band of microtubules at low temperature with pressure, (*e*) the marginal band of microtubules (arrow) at room temperature and 1 atm pressure and (*f*) the band (arrow) at room temperature and 5,000 pounds inch⁻² (34.48 N m⁻²) pressure. (*d-f*, $\times 23,830$).

example of the data thus obtained is shown in Fig. 1. In several cases, pressure decreased absorbance to the original value (that is, the value at room temperature), but, in some cases, pressure seemed to cause only a slight decrease in absorbance. In the same apparatus, pressure followed by cooling caused a smaller increase in absorbance than did cooling alone.

For verification, and as an independent check on these results, we also used transmission electron microscopy. A high pressure cell with a dual chamber (a modified form of that described in ref. 16) was used to fix the platelets under high pressure at a controlled temperature. Suspensions of platelet concentrate were maintained in one of the chambers, and a solution of 5% glutaraldehyde with s-collidine buffer was kept in the other. When temperature, time and pressure were appropriate, the fixative was mixed with the platelet suspension to give chemical fixing in the desired conditions.

Figure 2 shows typical results obtained when a batch of platelet concentrate was examined under four conditions. At room temperature the platelets were discoid with profiles in thin sections ranging from circular to elongated ellipsoid. Figure 2*a* shows a typical elongated profile of a fresh platelet. Beneath the generally smooth contour of the surface membrane was a marginal band of microtubules circumscribing the uniformly distributed vesicles and granules in the cytoplasm (Fig. 2*e*). When cooled, virtually all platelets become rounded, with irregular surface contours associated with the presence of numerous fine pseudopodia (Fig. 2*b*). The marginal band of microtubules was lacking and the membranous organelles and granules were grouped together

Fig. 3 Relative distribution of various shapes among platelets. 1, Definitely discoid, smooth membrane no pseudopodia; 2, round, smooth membrane no pseudopodia; 3, round, smooth membrane, one pseudopod; 4, irregular shape (caused by irregular membrane), no pseudopodia; 5, irregular shape and one or more pseudopodia; a, fresh platelets at room temperature and 1 atm pressure; b, platelets cooled to 2° C for 1 h after the application of 350 atm pressure; c, platelets cooled to 2° C for 1 h and then 350 atm of pressure applied for 1 h (while cool); d, platelets cooled to 2° C for 1 h at 1 atm pressure.

in the central area of the platelets. In conditions of low temperature with pressure or cooling followed by the application of pressure (Fig. 2c), the shapes of the platelets resembled those found in fresh samples at room temperature. Many platelets were clearly discoid with smooth surfaces and uniformly distributed organelles and granules. These discoid platelets had no marginal band of microtubules (Fig. 2d), although some were found in the central part of these platelets among the membranous organelles. Thus, microtubules do not seem to be essential to the maintenance of the discoidal shape of platelets under these conditions.

In an attempt to quantitate our results, we took photographs at low magnification and counted the platelets in each of five arbitrarily chosen categories based on shape and structure. The categories and their relative populations are presented in Fig. 3. About 93% of our fresh platelets fitted categories 1, 2 and 3, which were characteristic of normal fresh platelets. Treatment at 2° C for 1 h resulted in 25% platelets in categories 1, 2 and 3, and 75% in categories 4 and 5. More than 90% of the platelets cooled under pressure for 1 h fitted categories 1, 2 and 3, while 78% of those cooled for 1 h and then pressurised while cold for 1 h fitted categories 1, 2 and 3, with 22% in categories 4 and 5. Thus, it seems that pressure prevented the change in shape that typically occurs when platelets are cooled. Figure 3d indicates that pressure was less effective after cooling than before cooling.

In discoid cells maintained at low temperature under pressure there was no marginal band of microtubules (Fig. 2d) in contrast to platelets kept at room temperature and atmospheric pressure (Fig. 2e). To evaluate this further, platelets were fixed at room temperature under pressure, and examined with the electron microscope. In all cases, there was a marginal band of microtubules (Fig. 2f) indicating that, contrary to many suggestions¹⁷⁻²⁰ pressure alone in the ranges investigated did not cause disaggregation of the microtubules. Similar findings were obtained with microtubules from various nerve cells using the equipment described here²¹. The marginal band was generally not as clearly segregated into discrete bundles in these conditions as their counterparts at a pressure of 1 atm.

The fact that pressure definitely moderates the morphological changes caused by cooling, indicates that the use of physical methods (either alone or in conjunction with other methods) may lead to improved storage procedures for blood platelets. The measurement of some viability parameters of platelet samples subjected to various conditions of pressure and temperature is currently in progress.

Mechanism for oscillatory synthesis of cyclic AMP in *Dictyostelium discoideum*

CELLS of the slime mould *Dictyostelium discoideum* aggregate around centres into multicellular fruiting bodies as a chemotactic response to cyclic AMP (refs 1 and 2). The wave-like character of this phenomenon suggests the release of cyclic AMP pulses by the founder cells^{3,4}. In this respect, metabolic oscillations controlled by cyclic AMP have been observed in suspension cultures of *D. discoideum* cells capable of forming aggregates⁵. We present here a mechanism for both these intracellular oscillations and the periodic release of chemotactic signal by aggregation centres.

The mechanism is based on the regulation of two enzymes directly involved in the synthesis of cyclic AMP, ATP pyrophosphohydrolase (E_1) and adenylyl cyclase (E_2), which transform ATP into 5' AMP and cyclic AMP, respectively⁶ (see Fig. 1). In *D. discoideum*, this bienzyme system bound to the cell membrane is autocatalytically controlled: adenylyl cyclase is activated by 5' AMP whereas ATP pyrophosphohydrolase is activated by cyclic AMP (ref. 6). In both cases positive heterotropic interactions are highly cooperative, suggesting the oligomeric structure of the enzymes. The system is further coupled to a membrane-bound phosphodiesterase which transforms cyclic AMP into 5' AMP (ref. 7). Rossomando and Sussman⁸ have suggested that the above regulatory pattern plays a primary role in the periodicity of aggregation. We support this hypothesis by a model which shows that the regulatory properties of adenylyl cyclase and ATP pyrophosphohydrolase can give rise to sustained oscillations in the synthesis of cyclic AMP around a non-equilibrium unstable stationary state.

The variables considered in the model are the intracellular concentrations of ATP, 5' AMP and cyclic AMP. The destruction of cyclic AMP in the phosphodiesterase reaction is represented, for the sake of simplicity, by a linear term corresponding to a non-saturated Michaelian enzyme. The system is open, ATP being produced at a constant rate and 5' AMP being removed in proportion to its concentration; the only sink taken into

account for cyclic AMP is that of the phosphodiesterase reaction. As this paper deals with the molecular basis of cyclic AMP oscillations at the cellular level and not with the process of slime mould aggregation, the effect of diffusion is not considered. It should be stressed, however, that oscillations in the intracellular cyclic AMP concentration may result, through transport of this metabolite across the cell membrane, in a periodic release of chemotactic factor into the extracellular medium. The cooperative kinetics of ATP pyrophosphohydrolase and adenylyl cyclase is described by the concerted model of Monod *et al.*⁸, assuming that these proteins are allosteric dimers and that the substrate and positive effectors bind exclusively to the active (R) state of each enzyme. In conditions of a quasi-stationary state for the enzymatic species, the time evolution of the metabolite concentrations is then given by the differential equations^{9,10}

$$\dot{\alpha} = v_1 - \frac{\epsilon_1 \alpha (1 + \alpha) (1 + \gamma)^2}{L_1 + (1 + \alpha)^2 (1 + \gamma)^2} - \frac{\epsilon_2 \alpha (1 + \alpha) (1 + \beta)^2}{L_2 + (1 + \alpha)^2 (1 + \beta)^2} \quad (1a)$$

$$\dot{\beta} = \frac{\epsilon_1 \alpha (1 + \alpha) (1 + \gamma)^2}{L_1 + (1 + \alpha)^2 (1 + \gamma)^2} - k_1 \beta + k_2 \gamma \quad (1b)$$

$$\dot{\gamma} = \frac{\epsilon_2 \alpha (1 + \alpha) (1 + \beta)^2}{L_2 + (1 + \alpha)^2 (1 + \beta)^2} - k_2 \gamma \quad (1c)$$

where α , β and γ denote, respectively, the normalised concentrations of ATP, 5' AMP and cyclic AMP; L_1 and L_2 , and ϵ_1 and ϵ_2 , are, respectively, the allosteric constants and the normalised maximum activities of enzymes E_1 and E_2 . The source term of the substrate is denoted v_1 , whereas k_1 and k_2 are the rate constants for the sink of the products β and γ . Concentrations and kinetic parameters (v_1 , ϵ_1 , ϵ_2) are normalised by division through the appropriate Michaelian or dissociation constants of enzyme-metabolite complexes^{9,10}.

The system described by equations (1a-c) admits a stationary state (α_0 , β_0 , γ_0) for $\dot{\alpha} = \dot{\beta} = \dot{\gamma} = 0$, that is, when the following relationships are satisfied:

$$\beta = v_1/k_1$$

$$\gamma = [\epsilon_2 \alpha (1 + \alpha) (1 + \beta)^2] / [k_2 (L_2 + (1 + \alpha)^2 (1 + \beta)^2)]$$

$$[\epsilon_1 \alpha (1 + \alpha) (1 + \gamma)^2] / [L_1 + (1 + \alpha)^2 (1 + \gamma)^2] = v_1 - k_2 \gamma \quad (2)$$

The dynamic behaviour of the model depends on the stability properties of the stationary state (α_0 , β_0 , γ_0). The latter have been investigated using a normal mode analysis¹¹ after graphical resolution of equations (2) on a digital computer. The results of the stability analysis are indicated in Fig. 2 as a function of

Fig. 1 Mechanism for the oscillatory synthesis of cyclic AMP in *D. discoideum*, based on the activation of ATP pyrophosphohydrolase (E_1) by cyclic AMP and of adenylyl cyclase (E_2) by 5' AMP. Constants k_1 and k_2 relate to the 5' nucleotidase⁶ and phosphodiesterase reactions (see text).

Fig. 2 Domain of sustained oscillations (shaded area) as a function of ATP injection rate (v_1), adenylyl cyclase and ATP pyrophosphohydrolase activity. The diagrams are established for $L_1 = L_2 = 10^6$, $k_1 = k_2 = 0.1 \text{ s}^{-1}$, a , $\epsilon_1 = 10 \text{ s}^{-1}$; b , $\epsilon_2 = 10 \text{ s}^{-1}$. Outside the shaded area the system evolves towards a steady state corresponding to a constant intracellular cyclic AMP level and, in the case of a linear sink to the extracellular medium, to steady release of chemotactic signal.

adenylyl cyclase and ATP pyrophosphohydrolase activity, for varying ATP injection rate. Each diagram is divided into two domains: outside the dashed region, the system evolves toward a stable steady state, whereas in the shaded domain of temporal dissipative structures^{11,12}, the system undergoes sustained oscillations around a non-equilibrium unstable stationary state with unique amplitude and frequency (Fig. 3). The period of the phenomenon is extremely stable with regard to enzymatic activities and substrate injection rate; it varies by less than a factor of two in the oscillatory range of parameter v_1 and a similar variation obtains for ϵ_1 and ϵ_2 . The oscillatory domain of each enzyme activity extends over more than two orders of magnitude, in contrast to the narrow unstable range observed for the substrate input (Fig. 2). Increasing ϵ_1 , ϵ_2 or v_1 lowers the period, whereas the amplitude of the oscillations passes through a maximum with respect to v_1 and ϵ_2 and diminishes with increasing ϵ_1 from zero. The role of enzyme cooperativity in the mechanism of instability is illustrated by the fact that the oscillatory domain corresponds to large values for the allosteric constants L_1 and L_2 , of the order of 10^6 . Predictions as to the order of actual metabolite concentrations in the course of oscillations are beyond the scope of the present study and require a precise knowledge of *in situ* kinetic parameters of membrane enzymes E_1 , E_2 .

Despite its relative simplicity, the model yields a qualitative agreement with a number of experimental facts. The waveform of the oscillations in Fig. 3 accounts well for the pulsatory production of cyclic AMP observed in slime mould aggregation; on the other hand, the restricted range of the period corresponds quantitatively to the observation that founder cells in *D. discoideum* oscillate with a period of 3–5 min⁴. Both the pulsatory nature of the oscillations and the stability of the period result from the allosteric properties of the enzymes involved in the instability mechanism, as previously shown^{10,13} for phosphofructokinase in the case of glycolytic oscillations¹⁴.

The model also accounts for some of the experiments performed in cell suspensions. It should be stressed that these experiments⁵ suggest the existence of a metabolic oscillator controlled by cyclic AMP and the independent operation of an amplification mechanism, whose nature is still not clear, for the relay of cyclic AMP pulses^{3,4}. The latter process, linked to the membrane receptor for cyclic AMP, allows control of intracellular cyclic AMP synthesis by extracellular cyclic AMP. The response coupled to the cyclic AMP receptor is not considered in the model of Fig. 1, which relates only to the multi-enzyme oscillator, but provision is made for the model oscillatory system to react to externally added cyclic AMP as described below.

The interaction of cyclic AMP with the oscillating system has been studied experimentally in suspended cells by investigating the response to pulses or continuous injection of this metabolite.

Fig. 3 Sustained oscillations of cyclic AMP. The curve is obtained by integration of equations (1a-c) using the Continuous System Modelling Program on an IBM 370-165 computer, for the following set of arbitrary values of the parameters: $\epsilon_1 = 0.4 \text{ s}^{-1}$, $\epsilon_2 = 10 \text{ s}^{-1}$, $k_1 = K_2 = 0.1 \text{ s}^{-1}$, $v_1 = 0.5 \text{ s}^{-1}$, $L_1 = L_2 = 10^6$. Initial conditions: $\alpha = 8$, $B = 4$, $\gamma = 4$. The normalised concentrations of ATP (α) and 5' AMP (β), (not shown) oscillate in the range 15-67 and 0.6-18, respectively. Periodic variation of intracellular cyclic AMP may result in a periodic release of chemotactic factor as a result of transport across the cell membrane.

Continuous addition of cyclic AMP does not modify the period of the phenomenon until injection rates are reached which extinguish the oscillations⁵. Correspondingly, in the model, addition of a constant source term in the kinetic equation (1c) for γ changes the period by less than 5% below the value 0.1 s^{-1} in the case considered in Fig. 3; above this threshold, oscillations disappear as the system evolves towards a steady state. As to the effect of discontinuous cyclic AMP addition, computer simulations of the model indicate that pulses of γ in the first part of the period after a peak of cyclic AMP delay the oscillations, with a maximum effect near the middle of the period; a small advance in the phase is observed when the pulse is applied in the second part of the period. These results and the fact that the minimum phase shift is found in the vicinity of a peak agree with experimental observations⁵. The differential sensitivity of the adenyl cyclase oscillator to cyclic AMP suggests a molecular basis for the refractory period observed in the chemotactic signalling process during aggregation³⁻⁵.

Two further remarks can be made about the experiments in suspended cells of *Dictyostelium*. The fact that 5' AMP does not interact with periodic behaviour⁵, contrary to the predictions of the model, could result from the lack of a membrane receptor for this metabolite. On the other hand, the model suggests that oscillations observed in the cytochrome chain⁵ result from the periodic variation of ATP in the adenyl cyclase system.

As a result of the formation of 5' AMP from cyclic AMP in the phosphodiesterase reaction, oscillations still arise in the absence of ATP pyrophosphohydrolase as indicated in Fig. 2. Thus periodic behaviour may result from the regulatory properties of adenyl cyclase only, although the reverse is not true for the second enzyme. For $\epsilon_1 = 0$, the model yields a three-variable autocatalytic mechanism for glycolytic oscillations with activation of phosphofructokinase by AMP; α , β , and γ denote then the concentrations of ATP, AMP and ADP, respectively. This generalises the results previously obtained in a two-variable model¹⁰ for glycolytic oscillations and stresses the similarity between the oscillatory mechanism in glycolysis and cyclic AMP synthesis. No interference between these oscillatory phenomena can be expected in aggregating cells of *D. discoideum* since glycolytic periodicities in yeast and muscle are linked to the cooperative properties of phosphofructokinase^{10,11}, which is not allosteric in the slime mould¹⁵.

Non-oscillatory mutants of *D. discoideum*, such as *ap66* (ref. 4), and oscillatory mutants with altered periodic properties,

such as *Fr17* (ref. 16), presumably differ from the wild type in the regulatory properties of one of the enzymes involved in the unstable mechanism¹⁷. More specifically, the model suggests that non-oscillatory mutants may lack activation of adenyl cyclase by 5' AMP. Particularly relevant is the finding that the regulatory pattern observed in *D. discoideum* (Fig. 1) also obtains in *Polysphondylium violaceum*⁸. Oscillations with a period of 1.5 min have been observed during aggregation in this species¹⁸, suggesting that the chemotactic attractant in *P. violaceum* is a metabolite linked to the oscillating system.

At the supracellular level, some models for *D. discoideum* aggregation postulate the existence of an oscillatory source of cyclic AMP (ref. 19). The mechanism discussed here lends support to such a postulate. Moreover, equations 1a, b and c could be included, with the effect of diffusion, in a set of equations that describe the aggregating system²⁰. The model should then be extended to include a second mechanism for the relay of cyclic AMP pulses, linked to the membrane receptor for this metabolite. Wave-like aggregation should result.

This work was carried out during the tenure of an EMBO fellowship. I thank Drs S. R. Caplan, G. Gerisch, B. Hess, L. Segel and M. Sussman for discussions.

Ion movement across leukocyte plasma membrane and excitation of their metabolism

A PERTURBATION of the molecular organisation of the surface membrane of mammalian phagocytes leads to significant modifications of their metabolism and functions^{1,2}. These modifications include a rapid increase of oxygen uptake, of glucose oxidation by the hexose monophosphate pathway (HMP) and of hydrogen peroxide production¹⁻³; an enhanced turnover of membrane phospholipids⁴ and a degranulation with extrusion of lysosomal proteins from cells^{5,6}. The importance of this functional response of phagocytes is particularly evident when the alteration of their surface properties is caused by interaction with bacteria, which, on being engulfed, can be killed and digested by the toxic agents (for example, H_2O_2 , superoxide anions, cationic proteins and hydrolytic enzymes) produced and/or discharged into the phagocytic vacuole⁶⁻⁹.

The trigger of the metabolic excitation, which has puzzled several investigators in the past, has so far escaped identification. We have shown^{1,2} that concanavalin A (con A), both in solution and coupled to non-phagocytosable beads, induces a metabolic stimulation of leukocytes, which can be reversed by dislodging the cross-linking lectin from its membrane binding sites with appropriate sugars. We have suggested that the 'on-off' switch, operating at the level

of the leukocyte surface membrane, involves a process of association-dissociation of membrane protein subunits. The clustering of these subunits should lead to a local increase in membrane potential and/or permeability to ions^{1,10,11}. To test this hypothesis we have now studied the effect of lanthanum ion and some ionophores on the metabolism of polymorphonuclear leukocytes (PMNL). The rare earth cation has been shown to bind to cell membrane protein and to induce an ion redistribution across the membrane¹². The ionophores easily form complexes with alkali or alkali earth ions. The complexes freely diffuse across membranes, thereby mediating a passive transport of cations down their concentration gradient¹³.

The ionophores used were valinomycin and nigericin, which form lipid soluble complexes with monovalent cations^{13,14}; A23187, a carboxylic antibiotic which transfers Ca^{2+} and Mg^{2+} across biological membranes¹⁵; and X537A, another carboxylic antibiotic which binds and equilibrates both monovalent and divalent cations¹³. PMNL were isolated from peritoneal exudates of guinea pigs injected with sterile 1.2% caseinate 15–16 h earlier. Cells were suspended in either calcium-free Krebs-Ringer phosphate with 1.2 mM Mg^{2+} (KRP-Mg) or calcium-free Krebs-Ringer Tris with or without 1.2 mM Mg^{2+} (KRT-Mg and KRT, respectively). Tris buffer was used instead of phosphate to avoid formation of precipitates with lanthanum and calcium ions. Respiration of PMNL was monitored by means of a Clark-type oxygen electrode and glucose oxidation by counting $^{14}\text{CO}_2$ produced from labelled glucose¹. Stock solutions of the ionophores were prepared in dimethyl sulphoxide (DMSO), the final concentration of which in the cell suspensions never exceeded 0.5% (v/v).

About 2 min after the addition of lanthanum ions to PMNL suspended in KRT-Mg, there was a pronounced increase in cell respiration (Fig. 1). At the same time, the leukocytes underwent an activation of glucose oxidation which was measurable even at 10^{-5} M concentrations of La^{3+} (Fig. 2). The use of exogenous glucose labelled either in position 1 or 6 led to the conclusion that the only metabolic pathway activated was the HMP.

Also the addition of X537A to PMNL caused a very rapid and extensive enhancement in oxygen uptake (Fig. 1). Because of the response time of the oxygen probe used (90% in 10 s) and the time required to inject the ionophore into the cell suspension, we conclude that the onset of metabolic activation is almost immediate. On a concentra-

tion basis the stimulatory efficiency of X537A in KRP-Mg is far greater than that of valinomycin, nigericin or A23187. The stimulation of respiration by all these agents is not affected by 1 mM NaN_3 , thus ruling out an activation of the mitochondrial oxidative systems. In addition, the stimulation of oxidation of 1- ^{14}C -glucose, and not of 6- ^{14}C -glucose (Table 1), shows that the respiratory stimulation is linked to an increase in the rate of HMP.

As well as acting as ion carriers, the ionophores might exert their biological effects by a mechanism unrelated to the ion movement. At least for A23187 this possibility seems unlikely, in view of the results obtained in media containing different electrolytes. As shown in Fig. 3, when A23187 is added to PMNL suspended in KRT, a slight stimulation of respiration is observed. This activation is very likely due to calcium bound to leukocytes or present as a contaminant in the reagents used. In fact, if Ca^{2+} is added to the cell suspension before A23187, a much greater increase in the rate of oxygen uptake is obtained. A similar potentiation of the effect of the ionophore is also given by Mg^{2+} , which, on a concentration basis, is less active, however, than Ca^{2+} . This difference might be explained as the result of either the steeper inward gradient of Ca^{2+} concentration, or a higher sensitivity of the cytoplasmic target to Ca^{2+} than Mg^{2+} . A third possible explanation would be that high concentrations of magnesium ions displace Ca^{2+} from cell membrane binding sites, thereby making it available for complexing and transport by A23187.

Table 1 Effect of ionophores on ^{14}C -glucose oxidation by PMNL

	Rest (DMSO)	X537A	A23187	Valinomycin
1- ^{14}C -glucose	16,075	61,150	33,475	30,975
6- ^{14}C -glucose	115	110	90	90

Data are expressed as $^{14}\text{CO}_2$ c.p.m. per μCi ^{14}C -glucose per 5 min per 1×10^7 cells. DMSO, 0.25%; ionophores, 20 μM . For experimental details see Fig. 2.

The activity of the divalent cations might be linked to an exchange with alkali ions. A23187 catalyses a K^+ release from erythrocytes¹⁵ and the parotid gland¹⁶, which is greatly stimulated by calcium ions. A similar migration of cations might also take place in leukocytes. Indeed, valinomycin and nigericin, which equilibrate K^+ concentrations across various membranes, cause a moderate metabolic stimulation of leukocytes. The activity of valinomycin cannot be amplified by an uncoupler such as 2,4-dinitrophenol, which enhances K^+ efflux from erythrocytes¹⁴, or by inhibitors of ATPase such as oligomycin or ouabain. Further, there is no synergy between valinomycin and A23187. Thus, while a divalent cation¹⁷ is an essential element in eliciting the metabolic response, the question whether or not K^+ participates in the process still remains open. It is important to emphasise, however, that X537A, the only ionophore among those used which is capable of carrying both alkali and alkali earth ions, provides the most efficient stimulus. Further, La^{3+} , which is also a good stimulant, has been shown both to deplete Ehrlich ascites tumour cells of K^+ (ref. 12) and displace Ca^{2+} from various biological membranes¹⁷.

Changes in the intracellular concentration of calcium ions seem to control the activity of various secretory cells. For example, A23187 and X537A cause a release of histamine from mast cells¹⁸, by promoting Ca^{2+} influx and extrusion of secretory granules¹⁹. Woodin has shown that the exocytosis of granule proteins from leukocytes treated with leukocytidin is accompanied by loss of potassium and accumulation of calcium ions²⁰. It would be expected that at least some of the agents we have used are able to promote

Fig. 1 Stimulation of the rate of respiration of guinea pig polymorphonuclear leukocytes by La^{3+} or X537A. 2×10^7 cells were suspended in, a, 2 ml calcium-free Krebs-Ringer Tris buffer (KRT-Mg) or, b, 2 ml calcium-free Krebs-Ringer phosphate buffer (KRP-Mg), containing 0.2 mM glucose (37°C). The oxygen uptake was continuously recorded with a Clark-type electrode. LaCl_3 , 0.3 mM; X537A, 20 μM .

Fig. 2 Effect of lanthanum ions on the rate of ^{14}C -glucose oxidation by guinea pig polymorphonuclear leukocytes. 1×10^7 cells were incubated at 37°C in 2 ml of KRT-Mg, containing 0.2 mM glucose, in rubber-capped flasks. Different amounts of LaCl_3 were then added, followed by, a, $0.4 \mu\text{Ci}$ of ^{14}C -glucose or, b, $4 \mu\text{Ci}$ of ^{14}C -glucose. After 10 min, the reaction was stopped with 1 N H_2SO_4 ; $^{14}\text{CO}_2$ was collected in 20% KOH, present in the flask centre well, and counted by scintillation.

a release of lysosomal enzymes from PMNL. Preliminary experiments have shown that X537A causes a moderate exocytosis of β -glucuronidase from PMNL. The appearance of the lysosomal enzyme in the medium is associated, however, with a parallel leakage of cytoplasmic enzymes such as lactate dehydrogenase and glucose-6-phosphate dehydrogenase. As reported by Goldstein *et al.*²¹, A23187 exhibits a very slight potentiation of the release of β -glucuronidase from human PMNL in the presence of Ca^{2+} . Thus, the relationship between the stimulation of the PMNL oxidative metabolism by ionophores and the selective release of lysosomal proteins remains to be clarified.

Fig. 3 Effect of added Ca^{2+} and Mg^{2+} on stimulation of guinea pig leukocytes by A23187. 2×10^7 cells suspended in 2 ml of KRT, containing 0.2 mM glucose. A23187, $10 \mu\text{M}$.

In conclusion, all the results presented here may be used to build a model of metabolic excitation of leukocytes. It is tempting to hypothesise a single, unique mechanism responsible for all the effects evoked in PMNL either by phagocytosable matter or by other surface perturbing agents (anti-PMNL antibodies, phospholipase C, detergents, fatty acids, con A and so on)². The trigger mechanism would consist, in fact, in a rapid shift of divalent cations from the cell environment and/or from the plasma membrane binding sites towards special zones of the cytoplasm. Calcium ions are likely candidates for this task. Other ion species, possibly K^+ , would be released in the opposite direction at the same time. According to this picture the leukocyte excitation would follow a mechanism rather common to other excitable cells.

Admittedly, this hypothesis requires further experimentation. Measures of actual fluxes of ions, ion gradients and dependence of the metabolic effects on these parameters are now under way in our laboratory.

T-cell populations with different functions

VARIOUS functions have been ascribed to thymus-derived (T) cells, including the ability to synergise with B cells in antibody responses¹ and with T cells in the generation of effector functions (refs 2-4 and H. Cantor and E. Simpson, unpublished), cytotoxic activity⁵, and regulator or suppressor activity^{6,7}. T-cell subpopulations, defined by criteria such as quantity of cell surface 0 antigen, homing characteristics (H. Cantor and E. Simpson, unpublished) and sensitivity to the effects of adult thymectomy and anti-thymocyte serum^{2,8}, have been described, but the functions of given subpopulations are still unclear. It seems likely, by analogy with B-cell differentiation and commitment to antibody class, that T cells become committed to certain functions during differentiation. In the absence of markers for individual T cells and their products or functions, analysis of cell populations and their activities provide

* CBA/J spleen cells were sensitised to alloantigens either *in vivo* by grafting tail skin or *in vitro* by the Wunderlich and Canty¹² modification of the Mishell–Dutton culture system¹³. Some mice were primed with 100 µg alum adsorbed ovalbumin (OVA) plus pertussis. Recipients were 400 r X-irradiated CBA/J mice. All received, in addition to the helper cells shown in the first column, 40 × 10⁶ spleen cells from CBA/J mice primed with 100 µg alum-adsorbed DNP-KLH plus pertussis 4 weeks previously and treated with 0.3 ml rabbit anti-mouse thymocyte serum (ATS) intraperitoneally 48 h before transfer as a source of B-cell precursors. Boosting was with 2 × 10⁷ DNP-P815 or DNP-EL-4, or with 5 µg DNP-OVA given intraperitoneally. Mice were bled 10 d later and anti-DNP antibody was measured by a modified Farr technique¹⁴. Geometric mean antigen binding capacity (ABC) for groups of five mice was determined; the value in parentheses is the range enclosed by one standard error.

† Cytotoxicity = % specific lysis

$$\frac{^{51}\text{Cr released by sensitised cells} - ^{51}\text{Cr released by non-sensitised cells}}{^{51}\text{Cr released from } 4 \times \text{frozen and thawed targets}} \times 100$$

Titration of cytotoxic activity were performed according to the method of Canty and Wunderlich¹⁵ using a fixed number (5 × 10⁵) of ⁵¹Cr-labelled target cells and different numbers of attacking cells, usually 4 × 10⁵, 2 × 10⁵, 1 × 10⁵ and 0.5 × 10⁵ in 1-ml volumes using four replicates for each attacker: target cell ratio, that is attacker:target cell ratios of 8:1, 4:1, 2:1 and 1:1. Target cells were from the ascites tumours EL-4 (H-2^b) and P815 (H-2^d). Under the conditions used, cytotoxic activity was directly proportional to the attacker:target cell ratio. In this table, the figures for cytotoxic activity shown are for an attacker:target cell ratio of 8:1. Background spontaneous ⁵¹Cr release for P815 was 6.75% and for EL-4 was 4.35% (4 h assay).

‡ *In vitro* sensitisation: 20 × 10⁶ CBA/J spleen cells were cultured with 1 × 10⁶ 2500 r X-irradiated DBA/2N spleen cells in 1 ml volumes and collected after 5 d. Numbers of cells used in transfer refers to number of viable cells transferred.

§ P815 and EL-4 tumour cells were reacted with 1-fluoro-2,4-dinitrobenzene in isotonic carbonate-bicarbonate buffered saline, pH 9.3, at room temperature for 15 min and washed thoroughly to yield DNP-P815 and DNP-EL-4.

an approach to this question. Experiments of this type have dissociated helper and cytotoxic activity^{9,10}, and the 'unmasking' of nonspecific suppressor T cells was reported to follow the culture of helper cells with specific antigen¹¹. We have now dissociated helper activity and cytotoxic activity directed towards a given alloantigen following either *in vitro* or *in vivo* immunisation. We also found that nonspecific suppressor T cells arise during *in vitro* culture.

To investigate whether cytotoxic T-cell activity and helper T-cell activity specific for the same alloantigens occurred in the same population of sensitised T cells, CBA/J mice were sensitised to DBA/2 and their spleen cells were assayed simultaneously for cytotoxic and helper activity. In the experiment illustrated in Table 1, spleen cells from CBA/J mice immunised *in vivo* by skin grafting 13 or 28 d previously had no cytotoxic activity but did demonstrate substantial helper activity (lines 3 and 4 compared with lines 1 and 2). In other experiments, weak, variable cytotoxic activity was observed in spleen cells of skin grafted mice; this activity did not correlate with helper activity. *In vitro* sensitised spleen cells, however, had considerable cytotoxic activity (the small amount of activity against EL-4 was probably the result of H-2 determinants shared by H-2^b and H-2^d, but not H-2^k mice); such cells had no helper activity (line 5). To test for suppressor activity, small numbers of *in vitro* sensitised cells were mixed with active helper spleen cells from mice immunised *in vivo* before transfer. With 15 × 10⁶ *in vitro* sensitised cells the anti-DNP antibody response was 10% of the expected value (line 4 compared with line 6). The suppressor activity was apparently nonspecific, for 15 × 10⁶ *in vitro* sensitised cells had the same effect on the anti-DNP antibody response to DNP_s-OVA in recipients of OVA-primed helper cells (lines 7 and 8).

Further experiments to test the specificity of helper and cytotoxic cell activity and of the suppressive effect are shown in Table 2. In this experiment, spleen cells from CBA/J mice immunised *in vivo* with either DBA/2 or C57BL/6 antigens were transferred to irradiated recipients together with DNP-primed spleen cells and the appropriate antigen. *In vivo* immunised cells had helper activity specific for the priming alloantigen but

little or no cytotoxic activity (lines 2 and 3). When *in vitro* sensitised cells which had specific cytotoxic activity directed against the sensitising antigen were mixed with the *in vivo* primed helper cells before transfer, all anti-DNP antibody responses decreased (lines 4 and 5), and even greater suppressive activity was given by CBA/J spleen cells held in culture for 5 d with irradiated syngeneic cells (line 6). The suppressor activity was therefore essentially nonspecific both in induction and expression.

Finally, Table 3 shows that suppressor cells in the cultured spleen cell population are T cells. CBA/J spleen cells sensitised *in vitro* to DBA/2 antigens and showing cytotoxic activity against H-2^d target cells were tested as nonspecific suppressors *in vivo* by mixing them with DNP-KLH-primed and OVA-primed CBA/J spleen cells. The anti-DNP antibody response of the recipients to DNP-OVA was suppressed by the cultured cells (line 4 compared with lines 2 and 3) but this effect was abrogated by treatment of the cultured cells with anti- θ plus complement, which also substantially reduced their cytotoxic activity. This strongly suggests that the suppressive effect is a T-cell function.

Helper activity and cytotoxic activity are both T-cell functions and demonstrate specificity for antigen. The activities are dissociated in these experiments since immunisation regimes which favour the production of one apparently induce little of the other. The suppressor activity present in those populations with high levels of cytotoxicity could, however, mask the activity of helper cells induced in the same populations. While helper and cytotoxic activities are not manifest in the same populations and are probably functions of different T-cell subpopulations, the present evidence is not decisive. Nor do these data bear on the question of whether the cells with these effector activities are derived from the same or different precursor cells. Data obtained with anti-Ly antisera before and after sensitisation suggest, however, that helper cells and cytotoxic cells occur in different populations and are derived from different precursors (P. Beverly and H. Cantor, personal communications).

The suppressor activity we have described is also a T-cell function but differs from helper and cytotoxic activity in being nonspecific both in induction and expression. The suppressor cell generated by 4–5 d of culture under Mishell–Dutton conditions is interesting for several reasons. While Kontiainen and Feldmann¹⁶ have reported the generation of specific T helper cells in Marbrook cultures, helper cell generation in Mishell–Dutton cultures has not been observed. This failure may well be due to masking of helper cells by suppressor cells. Indeed, Kontiainen and Feldmann (personal communication) found that helper activity was optimal at 3–4 d of culture and declined thereafter, perhaps due to generation of suppressor cells. Furthermore, *in vitro* primary antibody responses tend to 'turn off' after 5–6 d even when the medium is changed regularly. This phenomenon may well result from supervening suppressor activity of the type we describe. Direct evidence that this

may be occurring has recently been provided by experiments in which the *in vitro* anti-DNP response to DNP–Ficoll, a T-independent antigen¹⁷, was prolonged solely by pretreatment of the cultured cells with anti- θ and C' (D. Mosier, personal communication). The suppressor cell, described by Pierce¹⁸ and Dutton¹⁹, that arises in spleen cells cultured for 2 d with concanavalin A may be the same type of cell; the concanavalin A might serve primarily to accelerate its activation. The stimulus for the generation of the nonspecific suppressor T cells observed in our experiments is not known, as alloantigens are not required. The foetal calf sera used in these experiments, however, while from several different batches, all contained those unknown features which make for good *in vitro* immune responses (R. I. Mishell, personal communication). Such materials have mitogenic potential and this may account for the generation of suppressive activity. In parallel experiments the T-cell nature and lack of specificity of this suppressor cell have been confirmed, using an *in vitro* assay for its activity. Furthermore, it has been shown to suppress the *in vitro* antibody response to a T-independent antigen, suggesting that it may act directly upon B cells (P. C. Marrack and J. W. Kappler, unpublished).

In conclusion, T cells with three distinct activities have been demonstrated and dissociated: antigen specific helper T cells, antigen specific cytotoxic T effector cells and nonspecific T suppressor cells. Our data do not show whether these populations come from a common precursor nor, if so, at what stage they differentiated into distinct sublines of cells.

Prolonged survival of muscle allografts in adult rats

ALLOGRAFTS from minced muscle tissue and free muscle grafts are retained, as are other types of allografts, if immunological tolerance is induced in the recipients by neonatal injection of antigen¹, but are rejected in untreated animals^{1,2}. Recovery of contractile and histochemical properties of the regenerating muscle fibres in such free muscle allografts in tolerant rats has been observed. This study was designed to determine the fate of free muscle grafts transferred to animals treated in adult life.

Rats of the AVN strain were immunised at the age of 2.5 months with antigen prepared from rats of the Lewis (Lew) strain, differing from the AVN recipients at the strong (H-1) and weak (non-H-1) histocompatibility loci. When the hydrocortisone injections were stopped, free grafts of the whole extensor digitorum longus (EDL) muscle were transplanted into the bed of the previously removed EDL muscle of the recipient. The tendon of the muscle was sutured to that of the removed muscle. The grafted fast EDL muscle undergoes a process of degeneration succeeded by regeneration during which it changes from the originally slow to a fast contracting muscle, and histochemically from a homogeneous to a mixed muscle fibre pattern. A detailed study of the changes in contractile and histochemical properties of such free grafts has been reported⁴. The recovery of grafted muscle may be complete with respect to twitch characteristics⁵ but rather incomplete with respect to weight and tetanic tension output and morphological changes⁴⁻⁷.

One group of AVN rats received transplanted muscles from Lew donors (H-1 and non-H-1 difference) and a second group from the congenic strain Lew.1A donors, differing from the AVN recipients only at the weak (non-H-1) histocompatibility locus⁸. Thirty days after transplantation and combined treatment, the EDL muscles were removed and their contractile properties studied *in vitro*. The muscles were set up in a chamber with platinum electrodes for massive stimulation⁹ at a temperature of 37°C and the contraction properties recorded using an automatic analyser¹⁰. Twitch tension, latency period,

Table 1 Contractile properties of free muscle allografts in treated animals

Type of graft	TT (g)	LP (ms)	CT (ms)	HRT (ms)	Tet.T. (g)	Weight of muscle (mg)
Lew.1A (n = 4)	2.70 ±0.63	2.95 ±0.22	17.95 ±2.01	22.50 ±2.01	10.70 ±2.86	47.05 ±9.24
Lew (n = 4)	1.46 ±0.37	2.70 ±0.30	17.38 ±1.93	22.60 ±2.93	6.03 ±2.11	46.50 ±15.05
Lew.1A + Lew	2.08 ±0.41	2.82 ±0.18	17.66 ±1.29	22.55 ±1.82	8.36 ±1.87	47.00 ±8.18

Treatment comprised immunisation of the recipients with donor antigen together with injections of hydrocortisone. Lyophilised spleen cells in saline were used as antigen and injected in fifteen doses five times per week, the first three doses being 3, 2 and 1 mg, respectively, and the subsequent doses, 0.8 mg. Hydrocortisone (Spofa, Prague) was injected in eight doses of 6.25 mg, each dose in 0.5 ml of distilled water. The first three injections were given on consecutive days and the subsequent five injections on alternate days³. Free allograft of the extensor digitorum longus muscle of weak (Lew.1A) or strong (Lew) antigenic difference transplanted into treated (hydrocortisone and injection of lyophilised spleen cells) rats (AVN). Data are given as mean ± s.e. Third row indicates results of both groups. TT, twitch tension; LP, latency period; CT, contraction time (time to peak); HRT, half relaxation time; Tet.T., maximal tetanic tension output.

Fig. 1 Cross section through EDL muscle allograft (Lew.1A) in treated animal (AVN) 30 d after transplantation, stained for succinic dehydrogenase activity.

contraction time (time to peak), half relaxation time and maximal tetanic tension output were recorded. The muscle regenerates were removed whole and frozen quickly in CO₂; transverse sections were cut using a cryostat at 20°C and stained for succinic dehydrogenase activity, adenosine triphosphatase activity at pH 9.5 and phosphorylase activity. In some cases, routine histological observations after formalin fixation, paraffin embedding and staining with haematoxylin and eosin, were also made.

Table 1 shows the results obtained 30 days after grafting. Regeneration and concomitant recovery of contraction properties of both types of grafted muscles were observed. There was no clear difference, however, between the two groups (n = 4 in each group), that is between those with the weak antigenic difference (non-H-1) and those with the strong antigenic difference (H-1). The pooled data of both groups (n = 8) do not therefore differ from those of the individual groups. Recovery of contractile properties is somewhat less effective than that in autografts or allografts in tolerant rats¹, the contraction times being slower and the maximal tetanic tension output being slightly smaller.

Figures 1 and 2 show the regenerating muscle fibres in cross section, stained for succinic dehydrogenase (Fig. 1) and adenosine triphosphatase (Fig. 2) activity. Untreated allografts are completely rejected (six out of six), the muscles being replaced by connective tissues and fat as described previously^{1,2}. Thus, pretreatment has a considerable effect on muscle allograft survival, although absolute survival time was not investigated. In preliminary experiments, to elucidate the mechanism of allograft survival, the serum collected from the treated animals, 45 days after muscle transplantation was transferred

Fig. 2 Cross section through EDL muscle allograft (Lew.1A) in treated animal (AVN) 30 d after transplantation, stained for adenosine triphosphatase activity.

in amounts of 4 ml per animal. The serum had no effect on allograft survival in the animals with the strong antigenic difference, so far tested. Allograft survival was, however, observed in some cases of animals with weak antigenic differences.

Recently, a case of a successful free autograft of skeletal muscle in man has been described¹¹. The possibility of muscle grafts in tolerant rats¹ and of inducing immunological enhancement of muscle allografts by the treatment described suggests the possibility of muscle grafting in man. Immunological enhancement of muscle grafts by the passive administration of specific antisera will be the subject of further studies.

Repair of potentially lethal radiation damage in mammalian cells is associated with enhancement of malignant transformation

THERE have been several attempts to define conditions necessary for the fixation of the transformed state in mammalian cells *in vitro*. The relationship between fixation and proliferation after treatment has been studied in cell cultures exposed to methylcholanthrene¹, X irradiation^{2,3} and SV40 virus⁴. Cells were exposed to the carcinogen while in the density-inhibited plateau phase of growth, and subsequently subcultured at low cell density so that they could resume cell division. Transformation frequency was always reduced by delaying subculture for 24 h or longer, suggesting that cells must divide soon after exposure to a carcinogen in order to fix the transformed state. No data were reported for subculture less than 24 h after treatment.

Recent evidence, however, has shown that important repair processes, reflected by marked enhancement in survival when subculture is delayed after irradiation, may occur in density-inhibited cells during the first few hours after treatment^{5,6}. We have now studied the dynamics of transformation during this interval; changes in survival and transformation frequency were compared. We hope this approach may offer insight into the interrelationships between the repair of lesions with the potential of being lethal to the cell, and the development or loss of the potential of a cell to become transformed.

We used a C3H mouse embryo-derived cell line (10T-1/2 clone 8) provided by C. Reznikoff and C. Heidelberger (McArdle Laboratory for Cancer Research, University of

Wisconsin). This cell line has been adapted for use in quantitative transformation studies by Reznikoff *et al.*⁷ who found no evidence for spontaneous expression of murine C-type virus in these cells⁸. Stock and experimental cultures were maintained in Eagle's BME supplemented with 10% heat inactivated foetal calf serum (both obtained from Grand Island Biological Co). Stock and experimental cultures were maintained as outlined by Reznikoff *et al.*^{7,8}, except that cultures were kept in large glass stock bottles and the medium was supplemented with penicillin (50 U l⁻¹). Plateau phase experiments were performed with cells held as confluent monolayers for at least 24 h. The medium was changed 24 h before irradiation of the cells.

Transformation was scored as outlined before^{7,9}. The tumorigenicity of radiation-transformed foci was established by reinjection of cloned foci into syngeneic mice (Table 1). All tumours grew to 2–4 cm in diameter, when the mice either died or were killed. Type I foci, or dense regions of cells seen on experimental plates, were not scored as transformed and were not tumorigenic. Type II and III foci were tumorigenic and were scored as transformants. No spontaneous transformation was seen on untreated control plates. The morphology and corresponding tumorigenicity data found with radiation-transformed foci are consistent with those of Reznikoff *et al.*⁷ for methylcholanthrene.

Figure 1 shows results of experiments in which cells were irradiated in the density-inhibited plateau phase, and subse-

Fig. 1 Survival and transformation frequency in 10T-1/2 C3H mouse embryo cells irradiated in the density-inhibited plateau phase of growth and subcultured at various times thereafter. ●, Surviving fraction after 1,200 rad; △, transformation frequency after 200 rad; ○, 300 rad; ×, 400 rad. The confluent monolayers were trypsinised at various times (0–48 h) after irradiation, and subcultured at a lower cell density to assay for transformation and survival. Irradiation was carried out with a Phillips MG100 unit (100 kV, 10 mA) with 0.795 mm aluminium filtration and yielding a dose rate of 83.5 rad min⁻¹. For the transformation assay, cells were subcultured at a density such that approximately 200–500 viable cells per 100 mm Petri dish resulted, regardless of treatment. The medium was subsequently changed twice weekly until confluence was attained, then weekly until termination of the experiment 6 weeks after subculture. Dishes were then washed with normal saline, fixed with Bouin's solution, rinsed in 95% ethanol and stained with trypan blue. Lower density plates were also seeded at each point to assay for cell survival (plating efficiency) by standard techniques.

quently held in plateau phase for various times before subculture to assay for either survival or transformation. The upper curve, which represents cell survival, shows that survival was enhanced markedly when cells were held in plateau growth for 2–4 h after irradiation. The lower three curves represent the transformation frequency seen in similar experiments following 200, 300 and 400 rad irradiation. Transformation frequency was enhanced when cells were kept in plateau phase growth for 2–4 h after irradiation. The curves for survival and transformation were remarkably parallel for the earlier time intervals. With longer periods in plateau phase growth, however, a decline in the transformation frequency per surviving cell was consistently observed.

As Fig. 1 shows, there was an apparent increase in the amplitude of the transformation-enhancement with increasing radiation dose. A similar result has been described for the enhancement of survival, where the effect is seen as a decrease in the slope of the radiation survival curve⁶. A dose of 1,200 rad was thus chosen for the survival experiment, as the greater effect at higher doses allowed the kinetics of repair with time to be more easily studied. For transformation experiments, 200–400 rad were used as doses in this range yield maximum transformation per surviving cell⁹. The observed enhancement of survival would be fairly small following these lower doses.

These results demonstrate a high degree of correlation between the repair interval leading to both maximum survival and transformation following X irradiation. This observation sheds a somewhat different light on the relationship between delayed subculture and transformation in density-inhibited plateau phase cells as described before^{1–4}. A comparison of the data for subculture at 24–48 h after irradiation with those for 0 time shows a continual decline

a molecular level by other investigators^{10,11}. They report a peak in transformation frequency after treatment of synchronised cells with a radiomimetic alkylating agent at a time in the cell cycle when DNA strand breaks were being repaired at a maximal rate. The transformation frequency was maximal in cells treated during the 4-h interval preceding the G1/S boundary¹¹. Likewise, the repair of potentially lethal radiation damage also seems maximal in the late G1 cell population¹², the population of cells which predominates in plateau phase cultures. Taken together, these findings further support the error insertion hypothesis.

If the cell does insert the error which ultimately determines the behaviour of the cell, it may also be able to go back over its DNA and delete previously inserted errors. To be consistent with our results, this reversal of inserted errors would have to occur before the first cell division after treatment. It would thus be reflected by the decline in transformation frequency observed as the time in the density-inhibited plateau phase is lengthened. This hypothesis would also be consistent with the findings of Todaro and Green⁴ who treated cells with SV40 virus and then allowed one round of division before blocking them in a density-inhibited state. Under these conditions, no decline in the transformation frequency was observed.

Obviously, there is need for further investigation of the role of cell proliferation and molecular repair processes in oncogenic transformation; plateau cultures as a model for *in vivo* transformation may be useful. Our results indicate, however, that placing cells under conditions which enhance survival may be detrimental to the cells in terms of transformation. Furthermore, they suggest that if exposure to a carcinogen *in vivo* is associated with an appropriate proliferative response, slowly proliferating or non-actively-cycling cell populations, frequent targets of environmental carcinogens, may be particularly vulnerable to transformation.

Table 1 Inoculation of C3H 10T-1/2 clone 8 normal and radiation transformed cells into syngeneic mice

Irradiation (rad)	Type of transformed colony	No. of cells injected per mouse	Tumour incidence (No. of tumours/No. of mice)
None	Normal cells	2–5 × 10 ⁶	0/4
600	III	2–4 × 10 ⁶	5/5
600	II	2–4 × 10 ⁶	3/4
600	I	2–10 × 10 ⁶	0/8
600	Normal (non-transformed)	2–10 × 10 ⁶	0/9

in the transformation frequency (Fig. 1). This finding is consistent with the observations with transformation induced by methylcholanthrene¹, radiation^{2,3} and SV40⁴, and with the hypothesis that if there is an interval after treatment during which a cell does not divide, it will repair the lesions or errors which would eventually lead to malignant transformation. The implication of this hypothesis is that the errors were produced as a consequence of the direct action of the carcinogen, probably on cellular DNA. Our data for repair intervals of less than 24 h suggest two alternative hypotheses: (1) errors may be inserted during the repair of radiation-induced lesions in the DNA; or (2) some severely damaged cells may repair sufficient damage to survive, but these survivors retain an unusually high risk of transformation. To explain the results in Fig. 1 by the latter hypothesis, however, the transformation frequency per cell among this repaired population would have to be three to four times the maximum frequency ever observed in irradiated cells not allowed to repair. The insertion of new errors during repair would thus seem a more reasonable explanation for the findings.

The question of whether transformation involves direct induction of the critical lesion, or whether the error is inserted in the DNA during repair, has been dealt with on

Heterotransplantation of *Theileria parva*-infected cells to athymic mice

CONGENITALLY athymic (nude) mice have been used for the heterotransplantation and maintenance of human tumours^{1–6}. In many cases aplasia of the thymus is sufficient to allow tumour growth and other immunosuppressive treatments are apparently unnecessary. Here we describe how infected cells taken from a fatal case of East Coast fever

(ECF), regularly produced tumour-like masses only in irradiated athymic mice.

ECF is a tick-borne disease caused by *Theileria parva*, an obligatory intracellular protozoan parasite which undergoes schizogony in bovine lymphoid cells and which, in infected cattle, causes lymph node hyperplasia of almost lymphosarcomatous proportions⁷. It is at present the most important cattle disease in East Africa⁸.

An outbred colony of athymic mice was established from stock supplied 9 months before experimentation, from the MRC Laboratory Animal Centre, Carshalton, UK. Mice were maintained as an isolated colony under conventional conditions; those used for experiments were 6–8 weeks old and were irradiated at 800 rad from a ⁶⁰Co source 1 h before inoculation.

A steer was experimentally infected with ECF⁹ and died 20 days later. Immediately after death one iliac lymph node and one mediastinal lymph node were removed aseptically and finely chopped in sterile Eagle's MEM with added heparin (20 IU ml⁻¹). The cell suspension was pipetted off, centrifuged at 1,000g for 10 min and the cell pellet resuspended in Eagle's MEM, supplemented with 20% foetal calf serum, L-β-asparagine and antibiotics¹⁰. Lymphoid cells (5.6 × 10⁶) were thus obtained, of which 72.5% contained *T. parva* macroschizonts and 4.0% contained microschizonts. For mouse to mouse passage, tumour-like masses were similarly treated, but after removal were trypsinised for 4 × 30 min in 0.25% trypsin at 37° C, before pelleting and resuspending in Eagle's MEM. All inocula of mice were of 5.0 × 10⁷ cells in 0.2 ml of medium, given subcutaneously behind the right shoulder.

Cells obtained from the infected steer were inoculated into each of five irradiated athymic mice, and five irradiated Swiss mice. The residual cells were set up in culture¹⁰.

Between days 8 and 9 after inoculation, subcutaneous tumour-like masses were detected at the site of inoculation in four athymic mice. These continued to grow until the mice died on days 12, 33, 38 and 40. Biopsies of the masses showed the continuous presence of morphologically-normal parasitised bovine lymphoid cells. At *post mortem* examination, extensive vascular spread of these cells was seen on examination of blood and organ impression smears. Such cells, and occasional free macroschizonts, were particularly common in the lungs and liver, but were also seen in kidney, spleen, brain and lymph nodes. The tumour-like masses were composed almost entirely of parasitised bovine lymphoid cells and microschizonts were quite common in the later stages of growth. Piroplasms invading mouse erythrocytes were occasionally seen. Karyology of cells from a mass from one of the mice showed parasites present only in bovine cells. Despite the extensive vascular spread of parasitised cells, no tumour-like masses were detected in other sites on either macroscopic or histological examination. No macroscopic evidence of residual thymus tissue was detected *post mortem* in any of the mice examined.

No tumour-like masses developed in any of the Swiss mice, but lymphoid cells put into culture grew immediately.

The mass from the athymic mouse that died on day 33 was removed and a cell suspension prepared, aliquots of which were inoculated as before into five irradiated athymic mice. All five mice developed tumour-like masses, and passage was continued in irradiated athymic mice. Six passages were carried out and parasitised bovine lymphoid cells survived continuously in the mice for 136 d. During this time 47 irradiated athymic mice were inoculated and 43 developed parasitised tumour-like masses at the site of inoculation. Four mice died before growth was detectable.

The behaviour of cells in mice was similar in all passages and no evidence of further adaptation of the parasite was observed.

At passages 4 and 5 cells were also inoculated into a total of 8 non-irradiated athymic mice; two of these mice

developed small transient tumour-like masses and one developed a large persistent mass similar to those seen in irradiated mice.

Many athymic mice died as a result of the high dose of irradiation, but in some cases death was associated with massive infiltration of parasitised cells both locally and vascularly. In these cases respiratory distress, caused by pulmonary invasion by parasitised cells, was commonly seen as a prelude to, and as a probable cause of, death. The masses, which sometimes exceeded 20% of body weight, occasionally became excoriated on the surface and avascular necrosis was common in the larger ones. There was, however, no evidence of regression or rejection.

In Swiss mice, features associated with malignant neoplasia of lymphoid cells were previously recorded, following inoculation of *T. parva*-infected lymphoid cells grown in culture^{11,12}. Our findings support the concept of neoplastic-like growth of *T. parva*-infected cells in mice and provide a further step towards developing a laboratory model for use in ECF research, for example in chemotherapy, cross immunity studies and in the isolation of field infections. The invasion of mouse erythrocytes by piroplasms of *T. parva* has not previously been reported, although infected erythrocytes have been noted in irradiated athymic mice inoculated with *T. parva*-infected bovine lymphoid cells grown in culture (unpublished data). This finding opens up the possibility of interesting tick transmission studies.

We thank Professor G. Mugera for allowing us irradiation facilities. The work was supported by the International Atomic Energy Agency. The project is supported by the United Nations Development Programme with the Food and Agriculture Organisation of the United Nations as the Executing Agency in cooperation with the East African Community.

Transplantation and preliminary characterisation of lymphocyte surface markers of Abelson virus-induced lymphomas

MOST murine lymphomas induced by commonly available murine leukaemia viruses (such as Gross passage A and Moloney leukaemia viruses) arise in the thymus, originating as thymocytes or thymus-derived (T) cells. The tumours thus usually carry the surface θ antigen², they rarely

Abelson virus was obtained from Dr L. Rabstein, passaged in BALB/cAnN mice as 10% (w/v) tumour extracts. The pools used had a plaque-forming titre of 2×10^6 MLV PFU per 0.1 ml as measured by the XC test⁷ and a tumorigenic dose 50 (TD₅₀) of 2×10^2 per 0.1 ml when injected in newborn BALB/c mice. All pools also contained the LDH virus (which is not necessary for lymphoma induction by Abelson virus). Newborn mice were injected with 0.05 ml virus intraperitoneally (i.p.). Tumours arose in lymph nodes, meninges and bone marrow 3-5 weeks after injection (column 1). For transplantation, tumour cell suspensions were injected intraperitoneally into female BALB/c mice 2-4 months old, some pretreated 7-28 d previously with 0.5 ml pristane intraperitoneally (in transplantation of plasmacytomas, the pretreatment interval does not seem to be critical for transplantation enhancement). Ten primary tumours were used as the source of malignant cells to inject 32 pretreated mice and 32 controls.

* Same tumour.

have B-cell surface markers such as the κ (light) chain. Abelson and Rabstein, however, reported a leukaemia virus that induces non-thymic lymphomas³⁻⁵, which we have now found to have surface κ chains under certain circumstances.

When we started this work, transplantation of Abelson virus-induced tumours had not been reported. We therefore pretreated the recipients of the transplants with 0.5 ml of pristane intraperitoneally, as this had been previously shown to enhance the transplantation of plasma cell tumours⁶. As Table 1 shows, pristane-priming makes a striking difference in the efficiency of transplantation and the pathology of the transplanted tumour. Of the control mice, not treated with pristane, only 1 out of 32 developed an ascites tumour while four others developed local needle-track tumours (the control mouse with ascites also had a needle-track tumour). Local needle-track tumours presumably represent cellular transplantation rather than local virus induction of tumour. Of more than a thousand mice injected by us with Abelson virus, none has ever developed a needle-track tumour. The other 27 control mice developed a generalised non-thymic lymphoma after a mean latent period of 44 d (range 32-60 d). The gross distribution and microscopic pathology of the lymphomas arising in this group of mice was identical to that which results from inoculation of the cell-free virus into adult BALB/c mice. The pathology of these mice, infected with virus as adults, differs from that of those infected with virus as newborns by its longer latent period and the rarity of cranial bulging and facial tumours. Since the transplanted tumours all actively produce virus, the late-arising tumours in the non-pristane-treated mice very likely represent fresh tumour induction by virus. The later time of onset (32-60 d) of these tumours corresponds to those previously published for virus-induced disease in adult BALB/c mice⁸.

On the other hand, 30 out of 32 of the pristane-primed recipient mice developed ascites tumours, most of them very rapidly. It should be noted that seven out of the ten primary tumours transplanted successfully as ascites tumours with mean latent periods of 9-14 d. Successful transplantation of three of the ten primary tumours took longer, with means of 25-29 d. Since we have never obtained tumours in primed mice or unprimed mice by straight virus injection in less than 20 d we conclude that, at least 7/10 primary tumours were successfully transplanted. More rigorous evidence that these tumours were indeed transplants rather than fresh virus inductions was provided by karyotyping four tumours which were transplanted into mice of the opposite sex (XX or XY karyotypes). Secondary

or later passages of tumour No. 10 and three others not listed in Table 1 were all the karyotype of the donor (primary) mouse. Thus, it seems that the pristane-primed mouse is a far superior recipient for the successful transplantation of this type of tumour.

One ascites tumour arising from the transplantation of each of the 10 primary tumours was studied for the presence of lymphocyte surface markers (Table 2). Each of the 10

The gamma globulin fraction of a rabbit anti-mouse κ chain anti-serum (a gift of Dr R. Mage) was conjugated with fluorescein isothiocyanate according to the method of Wood *et al.*⁹. Anti- θ C₃H was prepared according to the method of Reiff and Allen¹⁰. One-tenth millilitre of a cell suspension containing 5×10^6 tumour cells was incubated at 4°C with 0.1 ml of the fluoresceinated anti- κ reagent. The cells were then washed three times and one drop of the suspension was examined under ultraviolet light with a Leitz Ortholux microscope. If no immunoglobulin was detected with the direct technique by using the fluoresceinated anti- κ reagent, the tumours were then studied for the presence of the θ determinant by an indirect technique in which the cells were first incubated with the anti- θ diluted 1:10 as a middle layer followed by washing and then by the fluoresceinated anti- κ reagent. In this manner the fluoresceinated anti- κ reagent would bind to the κ chains of the mouse anti- θ antibody present on the θ -positive cells. For the detection of the C3 receptor of the B lymphocyte and the receptor for cytophilic antibody of the monocyte by red cell rosette techniques, the following reagents were prepared: 7SEA were prepared by adding the 7S rabbit anti-sheep cell antibodies (A) to sheep erythrocytes (E). 19SEAC were prepared by adding 19S rabbit antibody to E followed by an equal volume of fresh mouse serum (as the source of complement) diluted 1:10 in Veronal-buffered saline (VBS). These reagents were used as previously described¹¹. Rosette formation with the 19 SEAC reagent indicates the rosetted cells bear the C3 receptor of B lymphocytes; rosette formation with the 7S EA would indicate the cell had the cytophilic receptor of the monocyte. Under the conditions used the 7SEA reagent does not bind to the FC receptor of B cells¹⁰.

* One negative was a needle-track tumour.

† Abelson tumours not listed in Table 1.

transplanted ascites tumours listed in Table 1 as well as seven of the primaries and several other primary and transplanted tumours (shown as others on Table 2) was tested for the presence of surface κ chain. Seven tumours (Nos 1, 2, 5, 7 and three others) were also tested for their ability to form rosettes with EA or EAC. Six κ negative tumours (Nos 2, 4, 5, 7 and two others) were also tested for the presence of θ antigen. (The method used, indirect immunofluorescence, did not permit testing for θ in the presence of surface κ chain.)

The results of these tests were that all transplanted tumours had surface κ chain; 7 out of 25 primary tumours also had surface κ chain; 0 out of 6 tumours tested had θ antigen, and 0 out of 7 tumours tested formed rosettes with EA or EAC. These latter results indicated that the cells lacked the B-lymphocyte receptors for C3 and the monocyte receptor for cytophilic immunoglobulin.

The Abelson lymphomas are non-thymic in origin and, as demonstrated here, lack θ antigen; hence, they are unlikely to be derived from T lymphocytes. The basic question then is whether these cells are B-lymphocyte tumours, that is neoplastic derivatives of immunoglobulin-producing cells. The presence of κ chain on the surface of all the transplants and some of the primaries observed in this study suggests that this is indeed the case. It does not, however, prove that this surface immunoglobulin was synthesised by these cells. Another possibility is that the surface κ chains present on the tumours represent passively acquired host antibody directed against viral or tumour antigens on the surface of the neoplastic cells. While the data presented here do not rule out the latter possibility, we have in a separate report demonstrated IgM synthesis by long term tissue-culture sublines of tumour No. 5 (Table 1) (M.D.S., E. Premkumar, M.P. and P. Singer, manuscript in preparation). In addition, tumours No. 1 and No. 8 have also been shown to synthesise IgM (E. Premkumar, *et al.*, unpublished).

The results of this study together with the previous work⁴ on plasma cell tumour induction by Abelson virus indicate that this virus preferentially induces tumours in immunoglobulin-synthesising cells. The ability to obtain B-cell lymphomas rapidly, in great numbers, and perhaps with predetermined specificities, should be of great value to the cellular immunologist.

Local anaesthetics increase susceptibility of untransformed cells to agglutination by concanavalin A

CELL agglutination by concanavalin A (con A) is accompanied by redistribution of con A receptors on the cell surface from a random pattern to form patches¹⁻⁵. Differences in the susceptibility of untransformed and transformed cells to agglutination by con A may therefore reflect differences in the ability of receptors to move laterally within the membrane to form patches. For example, it has been suggested⁶⁻⁸ that the higher susceptibility of transformed cells to agglutination by low doses of con A might be associated with a more fluid lipid plasma membrane matrix. Enhanced fluidity of the bilayer matrix would allow greater lateral movement of receptors within the membrane and favour formation of patches of receptors after binding of con A to the cell surface. The increased susceptibility of L cell nutritional auxotrophs to agglutination by con A after enrichment of their membranes with fluid phospholipids⁹ supports this view. We report here that local anaesthetics which increase the fluidity of phospholipids in model membranes also cause a significant increase in the susceptibility of untransformed cells to agglutination by low doses of con A.

BALB/c mouse 3T3 cells, 3T3 cells transformed by SV40 (SV3T3), BHK cells and BHK cells transformed by polyoma virus (PY-BHK) were grown in Dulbecco's modified Eagle's MEM in 50 mm plastic Petri dishes (Falcon) as before¹⁰. Preparation of affinity-chromatography-purified con A, measurement of ³H-con A binding to cells and quantitation of cell agglutination have also been described previously⁴. Cells for freeze fracture studies were suspended in a solution of glycerol (30% v/v), sucrose (0.25 M) and Tris (5 mM), pH 7.2, and centrifuged; cell pellets were frozen rapidly in Freon 22 and cleaved in a Balzers BA 360 freeze-etching apparatus and shadowed with platinum as before¹¹.

Maximum agglutination of untransformed 3T3 or BHK cells by con A required significantly larger doses of con A than their virus-transformed derivatives (Table 1). Incubation of 3T3 and BHK cells with the local anaesthetic dibucaine for 60 min at 37°C however, significantly enhanced their susceptibility to agglutination by con A (Table 1). No significant change (<10%) in ³H-con A binding to dibucaine-treated cells was detected. The susceptibility of 3T3 cells to agglutination by low doses of con A (350 μ g ml⁻¹) has also been enhanced by treatment for 1 h at 37°C with the local anaesthetics tetracaine (1 \times 10⁻⁴ M) and procaine (1 \times 10⁻² M).

Some effects of local anaesthetics on membranes are believed

Table 1 Effect of dibucaine on cell agglutination by con A

‡ Cells were incubated in suspension in medium containing 1 \times 10⁻⁴ M dibucaine supplemented with 5 or 10 mM CaCl₂ for 1 hour at 37°C before testing for their con A agglutinability.

Fig. 1 Freeze-fracture electromicrographs (A face) of mouse 3T3 cells (100,000). The bar represents 0.1 μm . The arrows in the lower left corner of each micrograph indicate the direction of shadowing. *a*, Area of untreated control 3T3 cell showing predominant monogranular distribution of intramembranous particles. *b*, Area of 3T3 cell after incubation for 1 h at 37°C in medium supplemented with 1×10^{-4} M dibucaine showing increased clustering of intramembranous particles. *c*, Area of 3T3 cell after incubation for 1 h at 37°C in medium supplemented with dibucaine followed by incubation with 500 μg con A ml^{-1} for 15 min at 37°C, showing even more marked clustering of intramembranous particles than in (*b*).

to result from their ability to displace Ca^{2+} associated with the anionic groups of acidic phospholipids¹², and certain effects of these drugs can be inhibited competitively by increasing the Ca^{2+} concentration¹³. Similarly, incubation of 3T3 or BHK cells in medium supplemented with dibucaine plus additional Ca^{2+} (5 mM or 10 mM CaCl_2) eliminated the effect of dibucaine on cell agglutination by con A (Table 1).

Freeze-fracture observations of the surface of untreated 3T3 cells revealed a random and mostly single distribution of intramembranous particles (Fig. 1*a* and Table 2). After incubation with dibucaine, clusters of more than five particles were more common (Fig. 1*b* and Table 2). When similar dibucaine-treated cells were exposed to con A, more than 75% of the particles were clustered (Fig. 1*c* and Table 2). Thus, dibucaine causes a change in the structural organisation of the plasma membrane in 3T3 cells which is reflected in freeze-fractured images as redistribution of intramembranous particles, and this change is exaggerated in the presence of con A.

Electron spin resonance measurements on natural membranes¹⁵ and model membranes composed of phospholipid bilayers¹⁶ have shown that local anaesthetics increase the fluidity of phospholipids. Similarly, our data (in preparation)

from fluorescence polarisation measurements on dibucaine-treated cells—using the plasma membrane probe, diphenyl hexatriene⁷—suggests that dibucaine causes a small but significant increase in the fluidity of membrane lipids. It is not known whether this is a small change in the overall fluidity of the bulk lipid matrix or a much larger fluidity change in specific regions of the membrane. Differential scanning calorimetry and fluorescence polarisation studies on model bilayer membranes indicate that dibucaine causes a marked fluidising effect on several types of phospholipids (in preparation). At dibucaine concentrations (1×10^{-4} M) that enhance cell agglutination, however, this effect is confined to acidic phospholipids. This effect is more marked in acidic phospholipid membranes stabilised previously by Ca^{2+} , indicating that increased fluidity can also result in part from the displacement of membrane-bound Ca^{2+} by dibucaine. The same concentration of dibucaine caused no significant fluidity change in neutral phospholipids such as lecithin which constitute most of the plasma membrane lipids in mammalian cells. Thus, in intact cells low concentrations of dibucaine might induce a large fluidity change in specific membrane domains containing acidic phospholipids, without significant change in the fluidity of the bulk membrane lipid. Although such domains have not been demonstrated, experiments with mixed lipid bilayers indicate that Ca^{2+} can induce segregation of acidic phospholipids into separate domains from neutral phospholipids^{17,18}.

Table 2 Effect of dibucaine and con A on the density and distribution of intramembranous particles on freeze-fracture faces of 3T3 cell membranes

Treatment	Density of intramembranous particles (No. per μm^2)	Single	Distribution of intramembranous particles† (%)	
			Clusters < 5	Clusters > 5
Untreated control	495 ± 39	44.8	38.0	17.2
1×10^{-4} dibucaine‡	476 ± 23	21.9	41.6	36.5
1×10^{-4} dibucaine plus 500 μg ml^{-1} con A§	515 ± 35	23.5	28.7	47.8

* Mean value from counts of intramembranous particles on two or more 0.1- μm^2 surface areas of A fracture face of individual 3T3 cells at a magnification of 100,000 and counts on at least fifteen individual cells. These values are in good agreement with those reported by Scott *et al.*¹⁴.

† Percentage of total number of intramembranous particles.

‡ Cells were incubated with dibucaine for 1 h at 37°C.

§ Cells were incubated with dibucaine for 1 h at 37°C followed by addition of 500 μg ml^{-1} con A and further incubation for 15 min at 37°C.

In addition to the fluidising effect, displacement of Ca^{2+} might induce changes in the organisation of peripheral proteins on the inner face of the plasma membrane which have been suggested to act as regulatory restraints in determining the movement of receptors on the outer face of the plasma membrane¹⁹⁻²². For example, spectrin, which is involved in the trans-membrane control of lectin receptor site distribution in erythrocytes²⁰, is released from membranes by Ca^{2+} -chelating agents²³. Moreover, spectrin interacts with acidic phospholipids²⁴ at pH 7.4 only in the presence of Ca^{2+} . By competing for such Ca^{2+} -binding sites dibucaine could affect the interaction of peripheral spectrin-like proteins with membrane lipids.

The two mechanisms proposed here whereby local anaesthetics displace Ca^{2+} from acidic phospholipids and alter the function of certain peripheral proteins on the inner face of the plasma membrane could operate in parallel or in tandem. A framework of proteins on the inner membrane face exerting trans-membrane control of the topography of receptor moieties on the outer membrane face could be linked, as in the case of spectrin, to acidic membrane lipids by Ca^{2+} . This type of organisation could provide a mechanism for changes in the mechanical

properties of the plasma membrane regulated by Ca^{2+} , which would not require constant or extensive changes in the overall fluidity of the bulk lipid matrix of the membrane.

When this work was being prepared for publication, Ryan *et al.*²⁵ reported that local anaesthetics inhibited antigen-induced capping of immunoglobulin molecules on the surface of B lymphocytes. They found, however, that the formation of patches of Ig molecules, which is the process analogous to clustering of con A receptors on non-lymphoid cells, was not inhibited by local anaesthetics, but no data were given as to whether patching on lymphocytes was actually enhanced.

Asymmetry of influenza virus membrane bilayer demonstrated with phospholipase C

In the red cell, the membrane carbohydrates¹, proteins²⁻⁹ and lipids⁹⁻¹⁶ are all unequally distributed between the two sides of the plasma membrane. The membrane proteins and carbohydrates of influenza virions are also asymmetrically distributed^{16,17} (review in ref. 18). We have now found that the phospholipids of influenza virions are asymmetrically distributed as well. Using phospholipase C (PLase C) to digest the phospholipids exposed on the outer surface we have found a predominance of phosphatidyl choline (PC) and sphingomyelin (Sph) on the outer surface and a predominance of phosphatidyl ethanolamine (PE) and phosphatidyl serine (PS) on the inner surface. Since influenza virions acquire their lipid bilayer by budding out from the membrane of their host cells, it is reason-

able to surmise that this asymmetry characterises the host cell plasma membrane as well. Thus, the consistency between our present findings and previous findings with red cell membranes⁹⁻¹⁵ suggest that an asymmetric phospholipid distribution of this type may be a general feature of plasma membrane structure.

The WSN strain of influenza A₀ virus was grown in Maden bovine kidney cells, and purified as before^{19,20}, except that a constant specific activity of ³²P-inorganic phosphate (2-5 $\mu\text{Ci ml}^{-1}$) was maintained in the medium throughout the cycle of cell growth and virus infection and multiplication. This assured that all phospholipid synthesised during this period had identical specific activity. Spikeless particles, from which the glycoproteins had been removed by treatment with bromelain, were prepared as before^{16,20}.

PLase C of two specificities was used. PLase C from *Clostridium welchii* (Sigma) was dissolved (0.5 mg ml^{-1}) in 0.05 M Tris, 0.02 M CaCl_2 , pH 7.4, and heated at 95° C for 15 min before use²¹. PLase C from *Bacillus cereus* (Sigma) was dissolved (40 U ml^{-1}) in 0.05 M Tris, 0.01 M CaCl_2 , 0.01 M MgCl_2 , pH 7.4, and heated at 56° C for 30 min before use. One volume of enzyme was added to 4 volumes of viral particles in 0.05 M Tris, pH 7.4, and the mixture was maintained at 37° C for 60 min. These conditions were chosen after trichloroacetic acid (TCA) precipitation had shown that 45-55% of the total phospholipid was hydrolysed and additional incubation caused no further phospholipid hydrolysis. The virions were then resedimented in a 5-40% potassium tartrate gradient at 35,000 r.p.m. for 90 min in a Spinco SW 50 rotor. The enzyme-treated particles, whether intact or spikeless, and their respective untreated controls sedimented similarly and seemed unchanged when negatively stained specimens were viewed in the electron microscope. The purified virions were then extracted by the method of Folch *et al.*²². The extract was separated on silica gel thin-layer plates (Eastman Chromagrams) using the solvent chloroform-methanol-acetic acid-water (25:15:4:2)^{23,24}. After development, fractions from the plates were scraped into vials and radioactivity was counted. Approximately 90% of the total ³²P of the virions was recovered in the organic phase after extraction, and recovery of counts from the plates exceeded 95% of those applied.

Table 1 Hydrolysis of phospholipids from intact and spikeless influenza virions by PLase C

Phospholipid	% Hydrolysed		<i>B. cereus</i> enzyme
	<i>Cl. welchii</i> enzyme		
	Intact	Spikeless	
Sph	51	71	0*
PC	80	84	83
PS + PI	0*	0*	37
PE	43	56	42
Total hydrolysis	43	55	46

* Assumed as basis for calculation.

In Fig. 1a and b intact particles treated with the two types of PLase C are compared with their respective untreated controls. Figure 1c shows spikeless virus particles treated with the *Cl. welchii* enzyme^{16,20}. The results are tabulated in Table 1 based on normalisation to 100% recovery (that is, no hydrolysis of PS after treatment with *Cl. welchii* enzyme^{14,25} and 100% recovery of Sph after treatment with *B. cereus* enzyme¹⁵). Values of total hydrolysis obtained in this way (Table 1) are in good agreement with the values obtained by TCA precipitation of unhydrolysed phospholipids.

The patterns of hydrolysis by the two enzymes are quite similar if differences in the inherent specificities are considered. Both enzymes hydrolysed 80-83% of the PC of the intact virion and 42-43% of the PE. *Cl. welchii* enzyme hydrolysed 51% of the Sph from the intact virion, but 71% was removed from the spikeless particle. On the other hand, only 37% of the PS was hydrolysed by the *B. cereus* enzyme. This pattern of hydrolysis does not reflect the specificity reported previously for

Fig. 1 Thin-layer chromatograms of phospholipid extracts of influenza virions after treatment with PLase C. Extracts from enzyme treated and control preparations were chromatographed separately, but are plotted together to facilitate comparison. —, Untreated control; —, PLase C-treated. *a*, Intact virions treated with *Cl. welchii* enzyme; *b*, intact virions treated with *B. cereus* enzyme; *c*, spikeless particles treated with *Cl. welchii* enzyme.

these two enzymes, both of which have been reported to be fully active against PE, while the *B. cereus* enzyme is also active against PS^{14,15,25}. Indeed, the PE and PS in the particles are almost completely hydrolysed by the *B. cereus* enzyme under appropriate conditions, for example after prolonged storage resulting in particle deterioration, or if divalent cations are omitted from the reaction medium. The overall similarity between results obtained with intact and spikeless particles shows that the results do not reflect the protection of particular phospholipids by the glycoprotein spikes of the intact virion.

The interpretation of these results in terms of asymmetry of the viral bilayer depends critically on the assumption that the virion is impermeable to PLase C. Influenza virions are known to be impermeable to proteases and ribonuclease, strongly suggesting that they are impermeable to other enzymes as well. Further, our results were obtained only with virions which were repurified after treatment with PLase C, thus ensuring that any disrupted particles were removed before lipid analysis. Finally, the observation that additional time of incubation, or incubation with additional enzyme, produced no additional hydrolysis suggested that a stable situation was reached in the particle in which the unhydrolysed phospholipids were unavailable to the enzyme. The penetration of the enzyme to the inner surface of the viral bilayer thus seems very unlikely.

Although our results do not permit detailed quantitation of the lipid distribution of each side of the membrane, they indicate an asymmetric distribution. PC and Sph are preferentially located on the outer surface of the viral bilayer, where they are readily accessible to externally added PLase C, while PS and PE are less accessible to the enzyme, suggesting preferential localisation on the inner surface of the bilayer. We believe that more Sph than the 50–70% hydrolysed is located on the outer surface, since Sph is known to impart resistance to digestion by *Cl. welchii* enzyme²¹, and an increase in the total amount of Sph in the viral particle results in decreased hydrolysis of this phospholipid (J. L. and K.-H. T. unpublished). On the other hand, the finding that no more than 80–85% of the PC is susceptible to hydrolysis suggests the location of the remaining 15–20% on the inner surface, since this phospholipid is readily hydrolysed by both enzymes. The results also suggest that part of the PS and PE is located on the outer surface.

Extraneural competition between different scrapie agents leading to loss of infectivity

MANY strains of scrapie agent have been isolated which differ in their biological properties, such as incubation period and type of brain lesion¹. We have shown previously that competition occurred between different scrapie agents intracerebrally injected into mice², indicated by an increase in the incubation period of the lethal scrapie agent when a different scrapie agent had also been injected to impede its pathogenesis. We did not establish whether the increased incubation resulted from replication of the lethal agent being hindered throughout or at particular stages of pathogenesis, or whether the increased incubation period resulted from some loss of effective titre.

The pathogenesis of different scrapie agents injected into mice can only be described as relatively 'quick' or 'slow' if the recipient mouse genotype is specified in terms of the gene *sin*c (alleles *s7* and *p7*). On this basis, inbred mice can be injected with a 'slow' agent which can block, partially or completely, the pathogenesis of a 'quick' agent injected later by the same route. We have previously found that the effectiveness of blocking depends on the route of injection, the interval between injections and the particular strains and doses of agent used. We show that agent competition can be so effective in some circumstances that the 'quicker' agent, injected later, seems to take no active part in the disease and may have been entirely degraded or excreted.

RIII mice (3-4 weeks old) were injected intraperitoneally with either brain homogenate containing 22A agent, or with a similar dose of normal VM brain as controls. All mice received a second intraperitoneal injection of brain homogenate containing 22C agent, given either 100, 200 or 300 days after 22A (Table 1). The expected incubation periods for 22A and 22C given singly in these doses would be 550 days and 230 days, respectively. To calculate incubation periods when two agents are injected, we must be able to determine which agent eventually kills the mouse or, even, whether both share in this process. 22A and 22C are quite different in the intensity and distribution of brain lesions which they produce (ref. 3 and H.F., unpublished), and consequently the 'lesion profile' for each group in the competition experiment can be used to decide which origin to use for calculating incubation periods.

Table 1 Scrapie in RIIIrososines^{s7s7} mice injected intraperitoneally either with two different scrapie agents or with only one agent; the interval between injection of the two agents was varied

First injection:	Normal brain	22A
Second injection:	22C	22C
Injection interval (days)	Brain lesion profile type	Incubation period (days ± s.e.)
100	22C	237 ± 6 (7)
200	22C	232 ± 2 (7)
300	22C	231 ± 0 (5)
Injection interval (days)	Brain lesion profile type	Incubation period (days ± s.e.)
100	22A	554 ± 13 (6)
200	22A	557 ± 5 (9)
300	22A	561 ± 7 (7)

Number of mice in parenthesis. Doses: 22A agent-0.02 ml of 10⁻¹ saline homogenate from 22A-infected VM brain, containing 10⁶ VM intracerebral LD₅₀ units 0.02 ml⁻¹. 22C agent-0.02 ml supernatant (2,000g for 15 min) of 10⁻² saline homogenate from 22C-infected C57BL brain, containing 10^{3.7} C57BL intracerebral LD₅₀ units 0.02 ml⁻¹.

Table 1 shows that the 22A blocking injection was so effective that the second injection (22C) failed to infect the mice. The lesion profiles for the blocked and control groups are significantly different (method of least squares; *P* < 0.001) and the profile in the blocked animals confirms that 22A was responsible for killing the mice. If 22C does take an active part in the disease in the blocked groups, although subsidiary to 22A, we would expect variation between the results for the three sub-

groups with different intervals between injections: there was no evidence of such differences (incubation period *P* > 0.6; lesion profile *P* > 0.35). We do not yet have titration estimates in RIII mice of the number of intraperitoneal LD₅₀ units of 22A and 22C but the doses were at least 10^{1.5} and 10², respectively.

We regarded this as further support for the scrapie replication site hypothesis⁴, which proposes that replication of scrapie agents depends on a multimeric host site, to which different types of subunit are contributed by the two alleles of *sin*c, that there is a limit on the total available number of replication sites and that this total is relatively small. Agent competition is therefore envisaged as resulting from the agent injected first, having had the opportunity to occupy some or all the available sites, and thus blocking the access of agent injected later, even though the latter may be a much 'quicker' agent than the one already there. The total efficiency of blocking achieved in the above experiment also indicates that the rate of site turnover is low, and that production of new sites must be infrequent, unless the blocking agent has priority in access to them. The low turnover implies that the agent occupying the sites, and presumably also replicated there, must not, at any stage of the replication process vacate the sites, even transiently, to allow access of agent injected later.

Competition between scrapie agents able to replicate in mice, raises the question of whether site blocking could be achieved using related agents which do not seem to replicate in mice, such as the agents of kuru, Creutzfeldt-Jakob disease or transmissible mink encephalopathy. It may even be possible to block sites with simpler, non-replicating, molecules. To be of practical use in the control of such diseases, however, it must be assumed that the sites which these agents use are not essential to the normal health of the animal.

Relaxing and inotropic effects of cyclic AMP on skinned cardiac cells

THE positive inotropic effect of catecholamines in cardiac muscle is assumed to result from an increase in the intracellular level of cyclic AMP (adenosine 3',5'-monophosphate)^{1,2}. Cyclic AMP may enhance the contraction by increasing the trans-sarcolemmal flux of Ca²⁺ during the plateau of the action potential^{3,4}, but the flux seems insufficient to activate directly the myofilaments and it is generally assumed that additional Ca²⁺ may be released from intracellular stores (ref. 5), possibly by a Ca²⁺-triggered release from the sarcoplasmic reticulum (SR)⁶⁻⁸.

Whether the intracellular level of cyclic AMP can modulate this release of Ca²⁺ is not known. Furthermore, catecholamines increase the rate of relaxation in the intact myocardial tissue⁹. How cyclic AMP could mediate this relaxing effect has not been established, although studies in isolated cardiac microsomes suggest that cyclic AMP may enhance Ca²⁺ binding by the

SR¹⁰⁻¹³ Experiments on intact cardiac tissue cannot answer these questions, as both the relaxing and inotropic effects of catecholamines and cyclic AMP might be entirely the result of the modulation of Ca^{2+} fluxes across the sarcolemma³

We removed the sarcolemma by microdissection from fragments of single cardiac cells (less than 15 μm wide and 60 μm long) obtained by the homogenisation of rat ventricular tissues⁸ (Fig 1). This allowed the cyclic AMP added to the solution to be in direct contact with the SR and the myofilaments of these 'skinned' (sarcolemma-free) cells. The resulting inotropic and relaxing effects were observed on tension recordings obtained with a highly sensitive photodiode force transducer¹⁴ (Fig 1).

The free Ca^{2+} concentration ($[\text{Ca}^{2+}]$) in the bathing solution was buffered with ethyleneglycol-bis (β aminoethyl ether) N,N'-tetraacetic acid (EGTA). The same free $[\text{Ca}^{2+}]$ was obtained with either a low or a high total [EGTA] (Fig 1).

In the presence of a slight buffering with 5×10^{-5} M total EGTA cyclic contractions were induced by the increase of free $[\text{Ca}^{2+}]$ from 2.24×10^{-8} M to 3.16×10^{-7} M (Fig 1a). The amplitude of the cyclic contractions was much smaller when the same increase of free $[\text{Ca}^{2+}]$ was associated with an increase of total [EGTA] from 5×10^{-5} M to 1.5×10^{-4} M (Fig 1b). In the presence of 2×10^{-4} M or 4×10^{-3} M total EGTA, no cyclic contractions were observed and a tonic tension was induced by the same increase of free $[\text{Ca}^{2+}]$ (Fig 1c, d and e).

This experiment suggests that the cyclic contractions were caused by cycles of release and re-sequestration of Ca^{2+} by an intracellular pool of Ca^{2+} which was in competition for Ca^{2+} with the EGTA buffer present in the solution. When the total [EGTA] is high (4×10^{-3} M) any Ca^{2+} released or sequestered by this Ca^{2+} pool would not appreciably modify the free $[\text{Ca}^{2+}]$ present in the myofilament space. Thus the observed tonic tension represented the direct effect of the free $[\text{Ca}^{2+}]$ set in the solution on the myofilaments (Fig 1d). With a total [EGTA]

just above that which inhibited the cyclic contractions (2×10^{-4} M), however, the Ca^{2+} stores were still capable of competing with the EGTA. This competition was inferred from the slower rate of tension rise and lower plateau of tension as compared with that obtained with 4×10^{-3} M total EGTA (Fig 1c, e and d).

When 10^{-6} M cyclic AMP was added to the solution with 2×10^{-4} M total EGTA, a partial relaxation of the tonic tension was obtained and was followed by the development of cyclic contractions (Fig 1f). Conversely, removal of the cyclic AMP from the solution resulted in an increase of the tonic tension and in the disappearance of the cyclic contractions (Fig 1f). Similar results were obtained in all of the 22 experiments done according to this procedure. These results indicate that cyclic AMP increased the capacity for Ca^{2+} sequestration of the internal pool of Ca^{2+} , so that it could compete with larger total [EGTA].

In the presence of a free $[\text{Ca}^{2+}]$ of 2.24×10^{-8} M with 5×10^{-5} M total EGTA, a skinned cell was quiescent (Fig 2a). A slight increase of free $[\text{Ca}^{2+}]$ to 3.98×10^{-8} M was sufficient to induce a phasic contraction. Then the total [EGTA] was increased to 4×10^{-3} M so that the direct effect on the myofilaments of the free $[\text{Ca}^{2+}]$ set in the buffer could be studied in the same cell. A free $[\text{Ca}^{2+}]$ of 3.98×10^{-8} M (the same free $[\text{Ca}^{2+}]$ as that inducing the phasic contraction with 5×10^{-5} M of total EGTA) did not evoke any tension when the total [EGTA] was 4×10^{-3} M. Thus this free $[\text{Ca}^{2+}]$ was below the threshold for direct activation of the myofilaments. A free $[\text{Ca}^{2+}]$ of 3.16×10^{-7} M with 4×10^{-3} M total EGTA induced a tonic tension smaller than the phasic contraction obtained with a free $[\text{Ca}^{2+}]$ nine times smaller. This suggests that the phasic contraction was the result of a release of Ca^{2+} from the internal stores permitting the myoplasmic free $[\text{Ca}^{2+}]$ to reach a much higher value than that set in the buffer. This release of Ca^{2+} was induced by a slight variation of free $[\text{Ca}^{2+}]$

Fig 1 Tension recording in a single skinned cardiac cell of 10 μm width and 45 μm length from rat ventricle. All tracings were obtained from the same cell. Tracings d, e and f are continuous. Arrows indicate solution changes. Adult rats (200 g) were decapitated. The heart was rapidly removed and the ventricular tissue was homogenised with a Virtis blender. An aliquot of the homogenate was placed in a perfusion chamber on the temperature controlled stage of an inverted Reichert Biovert Microscope. One end of a broken cell was immobilised with a glass microelectrode, while another microelectrode was used to pull the sarcolemma and superficial myofibrils from the cell. The two ends of the skinned cell were impaled with glass microtools (heat occluded microelectrodes) in a direction perpendicular to the axis of the myofibrils. The myofibrils developed strong adherence to the glass. One of the microtools was immobilised while the other was connected to the lever of a photodiode force transducer¹⁴. Perfusion was accomplished by several inlets (one for each solution) and one suction outlet. All media contained glucose 7 mM and Tris-maleate 18 mM, pH was 7.0 and the

temperature was maintained at 22°C. The concentrations of Na_2EGTA , CaCl_2 , Na_2ATP and MgCl_2 were varied to obtain the desired free $[\text{Ca}^{2+}]$, while the free $[\text{Mg}^{2+}]$ was held constant at 3.16×10^{-4} M and $[\text{MgATP}]$ at 3.16×10^{-3} M. The ionic strength was kept constant at 0.16 M by appropriate addition of KCl. The following apparent association constants were used at pH 7.0: Ca-EGTA 4.9×10^6 M⁻¹, Mg-EGTA 40 M⁻¹, Ca-ATP 5×10^3 M⁻¹, Mg-ATP 11.4×10^3 M⁻¹. If the binding of Ca^{2+} by ATP was ignored, a simplified expression of the free $[\text{Ca}^{2+}]$ would be

$$-\log_{10} \text{free } [\text{Ca}^{2+}] \simeq 6.69 + \log_{10} \frac{\text{total } [\text{EGTA}] - \text{total } [\text{calcium}]}{\text{total } [\text{calcium}]}$$

Thus the same free $[\text{Ca}^{2+}]$ can be obtained with various levels of total [EGTA] by appropriate variations of total [Calcium]. The cyclic AMP was obtained from Sigma Chemical Co., St Louis, Missouri.

Fig. 2 Tension recording in a single skinned cell of 11 μm width and 52 μm length in the absence or in the presence of cyclic AMP. Arrows indicate perfusion changes. In addition to the experiments of the type represented in this figure, a curve of tension as a function of the free $[\text{Ca}^{2+}]$ was obtained, in the presence of 4×10^{-3} M total EGTA. The addition of 10^{-6} M of cyclic AMP did not change significantly any of the points on this curve.

in the buffer, consistent with a regenerative process⁶⁻⁸

The same series of perfusions were repeated on the same cell with the addition of 10^{-6} M cyclic AMP to the perfusion media. The resulting phasic contraction was of larger amplitude (increase of $78\% \pm 19\%$ (SD) for 18 experiments) with shorter duration (decrease of $17\% \pm 9\%$) and faster rate of tension development and relaxation than in the absence of cyclic AMP (Fig. 2b). In contrast, no modification of the tonic tension obtained in the presence of a high total [EGTA] was observed (Fig. 2b). Addition of 10^{-2} M azide (inhibitor of the respiration linked uptake of Ca^{2+} by the mitochondria) and of 10^{-6} M ruthenium red (inhibitor of the passive binding of Ca^{2+} by the mitochondria) modified neither the phasic contraction nor the effects of cyclic AMP. In contrast, the destruction of the SR by the non-ionic detergent Brij 58 (ref. 15) eliminated the phasic contraction and the effects of cyclic AMP. Therefore, the effects of cyclic AMP on the phasic contraction and relaxation of the skinned cardiac cells seem to be related to modifications in the release and binding of Ca^{2+} by the SR and not by the mitochondria.

In conclusion, cyclic AMP has been shown to modulate contraction and relaxation of single cardiac cells in the absence of the surface membrane. The relaxing effect of cyclic AMP in skinned cardiac cells is probably because of an enhancement of the capacity (Fig. 1) and the rate (Fig. 2) of Ca^{2+} binding within the SR. Additionally, the release of a larger amount of Ca^{2+} from more fully loaded Ca^{2+} stores within the SR in the presence of a higher level of cyclic AMP may explain at least in part the positive inotropic effect of catecholamines. In contrast, no direct effect of cyclic AMP on the sensitivity to Ca^{2+} of the myofilaments was shown in the present study.

Electrical activity and colonial behaviour in Anthozoan hard corals

ALTHOUGH colonial behaviour in the Anthozoa¹⁻⁴ has often been described, hypotheses relating the control of colonial polyp retraction to proposed nerve net activity have been based only on behavioural observations. This preliminary report of an electrophysiological investigation considers the conduction system controlling colonial polyp retraction in the Madreporarian coral *Porites porites* var. *clavaria*.

Single electrical stimuli of short duration at threshold level did not evoke any visible withdrawal response from any polyps. Two or more such stimuli applied at a single point within a second or two, however, always caused a colonial polyp retraction (Fig. 1). The retraction response was restricted to those polyps near to the point of stimulation and reached a maximum area of spread which was not exceeded even when large numbers of stimuli were applied. A colonial polyp retraction in response to a single shock could only be evoked when stimuli of longer duration were used.

A single stimulus at threshold level evoked a single impulse which was conducted to large areas of the surrounding colony. There was no evidence for multiple firing in response to stimuli of this kind. Figure 2 shows a typical electrical response given by *P. porites*.

In the sea anemones^{5,6} and the Octocorallia⁹, available evidence suggests that the nerve net is responsible for the control of polyp retraction and that nerve/muscle potentials are the most easily recorded electrical events. This suggests that the electrical activity reported here for the colonial Hexacorallia also involves a nerve net/muscle response, although it is possible that the system may be neuroid. Electrical pulses could be stimulated by either mechanical or electrical stimuli.

Fig. 1 Spread of colonial polyp retraction in *P. porites*, following repetitive electrical stimulation at a rate of 1 s^{-1} . r , radial distance of spread measured in polyp diameters, N , number of stimuli. Extracellular, polythene suction electrodes (see ref. 5) were used to record electrical activity. Similar electrodes were used to administer electrical stimuli. Each electrode was usually placed on the column or on the oral disk of a polyp.

The conduction velocity in the non-fatigued conduction system was $15\text{--}20\text{ cm s}^{-1}$ at 25°C and the amplitude of the recorded pulses was small ($5\text{ }\mu\text{V}$ or less) with a threshold of $4\text{--}5\text{ V}$ for stimuli of 1 ms .

Colonial pulses are normally through-conducted, an observation at variance with predictions for many Anthozoan corals^{4,7}. These predictions were limited by the nature of the observations which could be made at that time and, based on behavioural data, assumed that nerve-net pulses did not spread significantly outside the area visibly shown to respond. The paradox that electrical activity is normally through-conducted although the spread of the behaviour is restricted, requires explanation.

Control of fast muscle contraction in the Anthozoa depends on the phenomenon of neuromuscular facilitation⁸. To bring about colonial polyp retraction, therefore, a number of pulses must be conducted across the colony. Furthermore, the frequency of the pulses will determine whether or not retraction occurs at any particular point, since this will determine the degree of facilitation of the neuromuscular junctions.

In response to a burst of stimuli at constant frequency, a corresponding burst of pulses was elicited but not at a constant frequency. It decreased in response to (1) increasing distance from the point of stimulation, (2) increasing number of pulses (Fig. 3). A number of explanations are possible for the progressively increasing conduction delays of successive pulses. If a nerve net is involved, there may have been progressively increasing synaptic delays, or the conduction path may have become longer and less direct. The reduction in frequency was most pronounced where the pulses were close together.

Fig. 2 Recording of electrical activity (arrow) in *P. porites* following a single electrical stimulus (black spot).

in time, as the frequency of pulses decreased, the rate of slowing down decreased. The changes in conduction delay could account for the restriction of the area of polyp retraction because as the frequency of pulses progressively decreases the neuromuscular facilitation resulting from the preceding pulses decays before succeeding pulses arrive.

Horridge⁴ described patterns of polyp retraction in a number of colonial Alcyonarian and Madreporarian corals. He provided behavioural evidence showing that in some species (for example, *Favia*, *Coelaria*, *Goniastrea* and *Alcyonium*) all the polyps of the colony would retract in response to stimuli applied at one point, whereas in others (for example, *Porites*), the retraction response was restricted in spread and the whole colony was never involved in a colonial retraction response stimulated from one point. From these results, he developed a theory to predict the underlying nerve net events in terms of the 'density of active units' in a large array, and the probability of crossing from one unit to another. It was suggested that the size of contraction was related to the number of 'active units' (neurones or groups of neurones) in the nerve net at that point. Thus, in a region in which no contraction would take place, there was no reason to expect any significant amount of nerve net activity.

The results reported here fail to substantiate such a model or one based on the classic ideas of interneural facilitation. The different responses may be explained, however, as a function of the amount of delay introduced between electrical events conducted across the colony. The time intervals be-

Fig. 3 Increase in conduction time with repetitive electrical stimulation at a rate of 1 s^{-1} . D , Conduction delay (ms), N , number of stimuli.

tween successive pulses determine the degree of facilitation of the neuromuscular junctions and this in turn controls the size of the muscular contraction evoked. Further data for colonial members of the sub-class Hexacorallia and for members of the sub-class Octocorallia will be reported elsewhere^{9,10}.

Light autoradiographic localisation of cholinergic muscarinic receptors in rat brain by specific binding of a potent antagonist

THE presence of cholinergic muscarinic receptors on neurones in many regions of the mammalian brain is known from classical electrophysiological studies, which showed that neuronal firing rates are altered by the microiontophoretic application of cholinergic muscarinic agonists and antagonists¹. It is now possible to measure these receptors directly by biochemical procedures, some of which involve studying the responses of the cyclic guanosine monophosphate system in neuronal tissue to agonists and antagonists²⁻⁵. Other procedures utilised radiolabelled muscarinic agonists and antagonists that bind specifically and directly to presumed receptor sites⁶⁻¹². One of these agonists^{13,14}, 3-quinuclidinyl-benzilate (QNB) binds in a radiolabelled form to apparent muscarinic receptors *in vitro*^{6,7}. Recent experiments indicate that it is also possible to demonstrate specific ³H-QNB binding to cholinergic muscarinic receptors in rat brain *in vivo* soon after intravenous administration¹⁵. Because of this latter factor, we have been able to examine the *in vivo* localisation of ³H-QNB in regions of rat brains by light microscopic autoradiography. We have found receptor sites associated with various groups of cells, some of which are known to be cholinceptive. In general, the greatest densities of ³H-QNB sites were in telencephalic regions.

Six male Sprague-Dawley rats (180-220 g) were administered 180 μ Ci of ³H-QNB (4 Ci mmol⁻¹) by tail vein injection in 0.3 ml of saline and killed by decapitation 1 h later. Three animals were pretreated with atropine (50 mg kg⁻¹, intramuscularly), 30 min before injection of ³H-QNB. It was necessary to utilise atropine-pretreated animals since all QNB is not displaceable by muscarinic drugs *in vitro* or *in vivo*. Only the displaceable portion is pharmacologically relevant and of interest here^{6,7,15}. There was no metabolism of ³H-QNB in the brain at the time of death¹⁵. The brains were removed rapidly from the skulls and 2-5 mm slices of the appropriate regions were mounted on copper block supports and quickly frozen by partial immersion in liquid nitrogen or, in later experiments, in a propane-propylene (10/1) mixture at liquid nitrogen temperatures. Frozen coronal sections (4 μ m thick) of these tissues were thaw-mounted^{16,17} on to emulsion-coated (Kodak NTB 3) microscope slides and stored desiccated for 30 d at 2°C. After exposure, the slides were brought to room temperature, developed, fixed, immersed in Carnoy's solution (a histological fixer) and stained with pyronine Y. After drying they were mounted with Permount and observed with a Zeiss Universal microscope. Control slides prepared for positive and negative chemography showed no evidence of significant fading of latent images or spurious generation of grains after 60-d exposures. The overall autoradiographic procedure utilised in this study has been described previously¹⁶⁻¹⁸. We are also using other procedures^{17,19} which presumably would reduce further possible diffusion artefacts. Preliminary experiments, however, show results similar to those presented here. With regard to the problem of diffusion, a major factor in our favour is that the K_d for the QNB-receptor interaction is very low, 0.06 nM, and rate of dissociation of the QNB-receptor complex is correspondingly slow *in vitro*⁶ and *in vivo*¹⁵.

Of the areas examined, we found the highest densities of autoradiographic grains over the corpus striatum (nucleus caudatus-putamen), the cerebral cortex and the hippocampal

Fig 1 Light autoradiographs of regions of the brain. The grains are shown most clearly in (d) (arrow), a higher power micrograph of the striatum. Lower power micrographs are shown in (a), (b) and (c) to make the pattern of distribution more observable. Bars represent 25 μ m. a, Section of hippocampus proper showing pyramidal cells and adjacent areas in CA1. Note the high density of grains over regions on either side of the pyramidal cells, the stratum oriens (O) and the stratum radiatum (R), which contain the basal and apical dendrites of the pyramidal cells. The density decreases sharply at the boundary of (see arrow pointing along the boundary) and over the alveus (A), a fibre tract. b, Section of the dentate gyrus showing the granule cell layer and the adjacent areas, stratum moleculare (M) and stratum polymorphe (P). The stratum moleculare contains the dendritic processes of the granule cells, while the stratum polymorphe (this picture shows an area away from the pyramidal cells in CA4), is a heterogeneous zone containing the axons of the granule cells. Note the much higher density of grains in the region containing the dendritic processes. c, Same region as in (b) but from an atropine-pretreated animal. Note the great reduction in density of grains in the stratum moleculare, the dendrite-containing region while there is little or no change in the stratum polymorphe. d, Higher magnification of a section of the striatum, a region with a similar density of grains as that of the dendrite-containing regions of the hippocampus. The density was relatively uniform across the entire nucleus caudatus-putamen.

formation (Fig 1, Table 1). These results agree with our earlier *in vitro* and *in vivo* studies with rat brain^{6,15}. Apart from this more general evaluation, we were able to examine the distribution of grains in relation to specific types of cells known to have cholinergic muscarinic receptors. For example, the evidence is quite strong that acetylcholine is a neurotransmitter in septal afferents to the pyramidal and granule cells in the hippocampal formation^{20,21}. The cholinergic receptors on these cells are predominantly muscarinic, and most hippocampal cells were sensitive to acetylcholine, suggesting a widespread distribution of receptive areas²²⁻²⁴. While choline acetyltransferase and acetylcholinesterase are distributed very similarly in discrete layers in the hippocampus, acetylcholinesterase staining boutons do not seem to be layered, but are scattered diffusely throughout the tissue, suggesting that cholinergic terminals are predominantly axo-dendritic²³. Thus one would expect a widespread distribution of autoradiographic grains over regions containing dendrites of the pyramidal cells and perhaps also the granule cells. Our observations were consistent with these expectations. While these techniques do not permit visualisation of the dendritic processes, we found a high density of autoradiographic grains over the stratum oriens and stratum radiatum, regions containing the basal and apical dendrites of the pyramidal cells. The grain density seemed to be the same and relatively uniform in both of these regions, and was abruptly reduced at the boundary of and over the alveus, a fibre tract (Fig 1a). The grain density was also greatly reduced in these areas in atropine-pretreated animals, indicating that most of the ³H-QNB binding in these

areas was the specific, pharmacologically relevant binding. The stratum moleculare of the dentate gyrus, a region containing the dendritic shafts of the granule cells, also exhibited a high grain density. The density decreased abruptly at the ventral boundary of the dentate gyrus and was reduced in the stratum polymorphum, a heterogeneous zone containing the axons of the granule cells (Fig 1b). The grain density in most sections was distributed evenly across the stratum moleculare, but in more posterior sections it was much higher near the granule cell bodies and much lower in the outer regions of the stratum moleculare. The density of grains in these regions was markedly reduced in sections from rats pretreated with atropine indicating the presence of many receptors (Fig 1c). For example, when examined quantitatively, the stratum moleculare had 11.4 ± 0.65 grains per $100 \mu\text{m}^2$ in normal tissues, and 2.85 ± 0.53 grains per $100 \mu\text{m}^2$ in atropine-pretreated tissue. The background density found on the slides, off but near the tissue, was 0.33 ± 0.05 grains per $100 \mu\text{m}^2$ (data are mean \pm s.e.m. from six slides of three animals).

We also sampled several other regions of the rat brain (Table 1). In the corpus striatum, a region where most cells are sensitive to iontophoretically applied acetylcholine²⁵⁻²⁷, and where there is also a high level of muscarinic receptors^{7,12}, we observed a high density of autoradiographic grains. This density was relatively uniform and high across the entire nucleus, suggesting a lack of clustering of cholinergic cells. When examined quantitatively, the density of grains was more than four times higher between cells than over cells (12.9 grains per $100 \mu\text{m}^2$ compared with 2.96 grains per $100 \mu\text{m}^2$), again suggesting a localisation to dendritic processes (Fig 1d). The density of grains was much diminished over adjacent areas of white matter such as the corpus callosum and the bundles of internal capsule fibres. Even though the density of grains in the white matter was very low, it sometimes seemed to be reduced by atropine, in agreement with *in vitro* studies^{7,12}. It has been suggested that the binding sites in white matter areas are receptors localised on axons of cholinergic neurones¹².

In the cerebral cortex, the number of cells electrophysiologically sensitive to acetylcholine depends on the location explored^{28,29}. In this study, we observed variations in the density of grains in various regions of the cortex. There was a high density over cingulate areas and around cells in the pyriform cortex but a lower density at intermediate depths from the

surface (Table 1). In general, the density was greatly reduced in sections from atropine-pretreated animals, just as in the other regions.

The high densities observed in these regions differ from the lower density found around cells in various nuclei in the thalamus, hypothalamus, midbrain, medulla and cerebellum (Table 1). Perhaps cholinergic receptors in these regions are pharmacologically different from the QNB-type sites.

Thus it seems that one can associate these QNB binding sites with groups of cells in various brain regions. These findings would be useful for exploring the full significance and function of these presumed receptors. We are extending these studies so as to document more completely the distribution of these sites, to quantitate the distribution, and to examine the pharmacology of these presumed receptors in detail by electrophysiological methods.

Table 1 Relative density of autoradiographic grains in representative brain regions

Region	Relative grain density
Hippocampus	
Stratum oriens	++++
Stratum radiatum	++++
Stratum moleculare	++++
Alveus	+
Striatum	++++
Cerebral cortex	
Cingulate cortex	++++
Pyriform cortex	+++
Intermediate depths of cortex	++
Thalamus	
Lateral thalamic nuclei	++
Nucleus parafascicularis	++
Medial habenular nucleus	++
Hypothalamus	
Arcuate nucleus	++
Dorsomedial nucleus pars ventralis	++
Midbrain	
Raphe nucleus	+
Interpeduncular nucleus	+
Cerebellar cortex	0 to +

Relative densities were determined by examining the brain regions after exposure for 30 d. Densities refer to specific binding as they are corrected for blank values obtained by examining similar regions from atropine-pretreated animals. Relative grain densities for cerebral cortex and striatum were measured on coronal sections of rat brain showing Brodmann's area 6 of the cerebral cortex.

Antagonism of tolazoline by histamine H₂-receptor blockers

TOLAZOLINE (2-benzyl-2-imidazoline), a peripheral vasodilator and adrenergic blocking agent used to treat peripheral vascular disease and (formerly) hypertension, has actions similar to those of histamine, including vasodilation, pressor responses in the rabbit and stimulation of intestinal smooth muscle, gastric secretion and the heart. The cardiac stimulation has usually been referred to as sympathomimetic. Tachycardia and gastrointestinal distress are prominent clinical side effects of tolazoline. It has been used in place of histamine as a diagnostic agent for gastric function^{1,2}. The effects of tolazoline on gastric acid secretion and heart rate have, however, not been explained adequately in terms of mechanism or receptor theory. We have now been able to investigate this aspect using two specific H₂-receptor antagonists³, burimamide and metiamide. Our results indicate that the actions of tolazoline on sinus rate and

gastric acid secretion can be classified as H_2 -histaminergic. Recognition that tolazoline interacts with specific histamine receptors helps to explain why the drug has so many diverse actions affecting almost every organ in the body.

To investigate the influence of H_2 -receptor antagonists on tolazoline-induced gastric acid secretion we used female beagles with chronic gastric fistulae. Dogs were fasted overnight and prepared for intravenous infusion. Tolazoline was infused throughout the experiment, and gastric juice was collected every 15 min, the volume was measured and an aliquot was titrated with base to determine acid concentration. Burimamide or metiamide was dissolved in saline containing an equivalent of HCl and administered intravenously immediately after the seventh collection period (105 min) when secretion had reached a plateau.

Metiamide and burimamide, in doses which produced no other observable effects, significantly decreased both the gastric acid concentration and the volume secreted in response to tolazoline ($20 \mu\text{mol kg}^{-1} \text{h}^{-1}$). As Fig 1 shows, metiamide ($20 \mu\text{mol kg}^{-1} \text{h}^{-1}$) promptly decreased acid secretion for about 2 h, with a peak effect of nearly complete abolition of output. Half this dose elicited a similar response lasting about 1 h with a peak of 70% reduction in acid concentration. Burimamide ($20 \mu\text{mol kg}^{-1}$) also promptly decreased secretion for about 1 h, with a peak of 80% reduction. Thus, low doses of two H_2 -receptor antagonists markedly inhibited the near-maximal effect of tolazoline on gastric acid secretion. Under similar conditions, pyrilamine, an H_1 -receptor antagonist had no

Fig 1 Effect of H_2 -receptor antagonists on gastric acid secretion induced by infusion of tolazoline in dogs. Tolazoline was infused intravenously continuously beginning at time 0 at a rate of $20 \mu\text{mol kg}^{-1} \text{h}^{-1}$ in saline (20 ml h^{-1}). Effect of metiamide, $10 \mu\text{mol kg}^{-1}$ (○) and $20 \mu\text{mol kg}^{-1}$ (●), on acid concentration (mean \pm s.e.m., $n = 4$ each dose). Effect of burimamide, $20 \mu\text{mol kg}^{-1}$, on acid concentration (mean \pm s.e.m., $n = 2$).

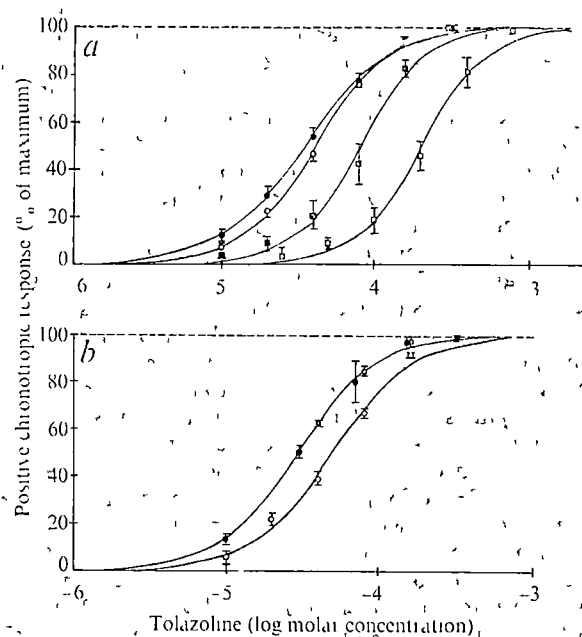

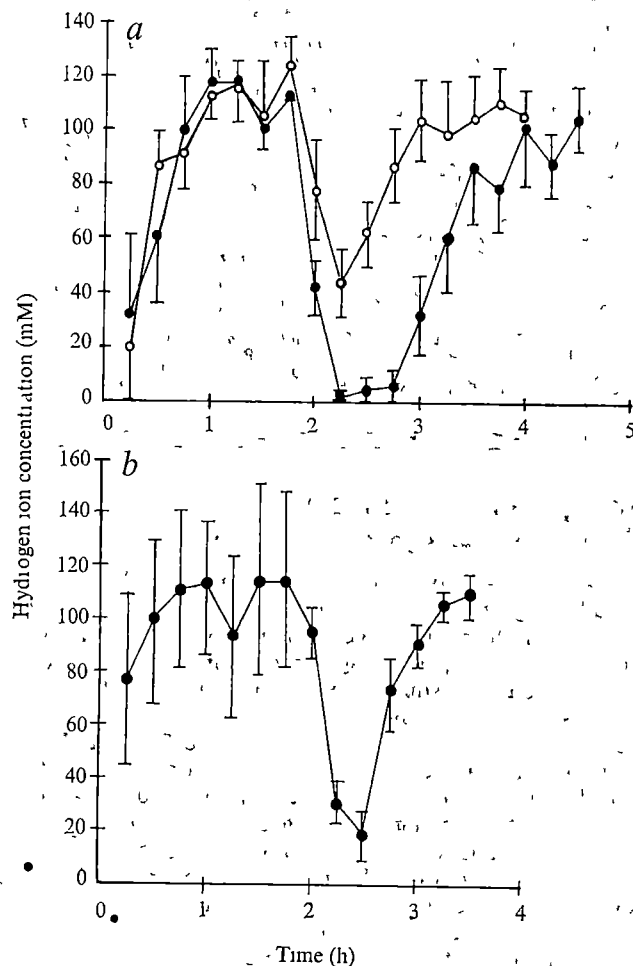

Fig 2 Effect of H_2 -receptor antagonists on the positive chronotropic response of guinea pig atria to tolazoline. The nonlinear least squares estimation program NONLIN (ref. 8) was used to fit the log dose-response curves to the logistic function⁹

$$\frac{y}{Y} = \frac{c^n}{c^n + K^n}$$

where y = response, Y = maximum response, c = drug concentration giving response y , $K = \text{ED}_{50}$, and n = numerical function of the slope of the dose-response curve at the ED_{50} level. The mean response \pm s.e.m. is plotted for each tolazoline dose. **a**, Response without antagonist (●, $n = 17$) and after equilibration with metiamide at $0.2 \times 10^{-6} \text{ M}$ (○, $n = 6$), $1.0 \times 10^{-6} \text{ M}$ (■, $n = 6$), and $4.0 \times 10^{-6} \text{ M}$ (□, $n = 6$). **b**, Response without antagonist (●, $n = 6$) and after equilibration with $2.0 \times 10^{-6} \text{ M}$ burimamide (○, $n = 6$).

effect. Our results suggest the involvement of H_2 -receptors in the secretagogue activity of tolazoline.

To investigate whether the cardiac effects of tolazoline might also be mediated by specific histamine receptors^{5,6}, and to provide more rigorous evidence on the mode of action of tolazoline, we studied the effects of tolazoline on heart rate in relation to cardiac H_2 -receptors identified by Black *et al.*³ and Parsons.⁷ We measured the activity of tolazoline on contraction frequency of spontaneously beating atrial pairs, and its antagonism by metiamide and burimamide. Male guinea pigs (500–700 g) were stunned by a blow to the head and killed by exsanguination. The heart was removed immediately and placed in oxygenated (95% O_2 , 5% CO_2) Krebs-Henseleit buffer (pH 7.4). Both atria were dissected rapidly and suspended at 1 g tension in a thermostatically controlled (30°C) tissue bath (50 ml) of the same oxygenated buffer. Tissues were allowed to stabilise, with repeated washing, for 1 h. Individual contractions were recorded with a force-displacement transducer through a strain gauge coupler, and instantaneous rates were obtained with a cardiometer. Cumulative dose-response curves were constructed after sequential additions of tolazoline as a concentrated solution in saline so that the total added volume was less than 1% of bath volume. Heart rate was allowed to stabilise before addition of each subsequent dose. After a dose-response curve in the absence of antagonist had been obtained, tolazoline was washed out until the rate returned to baseline. The procedure was then repeated after equilibration ($\geq 10 \text{ min}$) with the appropriate concentration of antagonist. The positive chronotropic response was defined as the increase over baseline rate just before addition of tolazoline. The baseline rate of 115 ± 2 beats per min ($n = 50$) was unaffected by burimamide or metiamide in the concentrations used. Maximal

rates in response to tolazoline (180 ± 3 beats min^{-1} , $n = 26$) were invariably lower than those observed with histamine under the same conditions (211 ± 3 beats min^{-1} , $n = 30$), and with tolazoline above $400 \mu\text{M}$, both rate and amplitude of contraction were depressed from their maxima. To normalise variations among tissues, responses are reported as percentage of the maximum increase, calculated for each preparation.

Metiamide, a competitive antagonist of histamine⁷, caused a parallel displacement of the tolazoline dose-response curves obtained with guinea pig atria (Fig. 2). Maximum responses were unchanged, and analysis of variance of the slope function, n , showed no significant difference in the slope of the curves. Ratios (DR) of doses needed for equal responses before and after equilibration with metiamide (Met) were calculated from the ED_{50} values and plotted according to the equation for competitive antagonism

$$\log(\text{DR}-1) = \log(\text{Met}) - \log K_B$$

where K_B = apparent dissociation constant for the antagonist-receptor complex¹⁰. The slope of the linear regression of $\log(\text{DR}-1)$ on $\log(\text{Met})$ was 1.07, not significantly different from the theoretical value of 1. The K_B for metiamide, calculated according to Waud and Parker⁹, was $8.5 \times 10^{-7} \text{M}$ ($pA_2 = 6.1$) at 30°C , in good agreement with the value obtained by Parsons⁷ ($K_B = 9.2 \times 10^{-7} \text{M}$, $pA_2 = 6.0$ at 34°C) using histamine as agonist. According to Schild's criteria for classification of receptors^{11,12}, tolazoline and histamine appear to bind to the same receptors. As a point of interest, our ED_{50} values for the positive chronotropic response to tolazoline and to histamine were $35.2 \pm 1.2 \mu\text{M}$ ($n = 17$), and $1.2 \pm 0.2 \mu\text{M}$ ($n = 24$), respectively.

Burimamide also inhibited the positive chronotropic response to tolazoline. The curves shown in Fig. 2 were constructed from data obtained in two experiments using three atrial pairs in each. Burimamide at a concentration of $2.0 \times 10^{-6} \text{M}$ caused a parallel shift to the right of the dose-response curve by a factor of 1.8 and had no effect on the maximum response. The single dose ratio calculated from these data (assuming slope = 1, $pA_2 = 5.5$ at 30°C) falls within the 95% confidence limits reported by Black *et al.*³ for burimamide using histamine as agonist.

In addition to its effect on heart rate, tolazoline increased the amplitude of contraction which was antagonised by both burimamide and metiamide. Although we did not analyse the amplitude data quantitatively, it seems likely that the positive inotropic effect of tolazoline is mediated by H_2 -receptors, as shown for histamine¹³. The actions of tolazoline on cardiac rate and contractility were unaffected by the β -adrenergic receptor blocker, propranolol (10^{-6}M), or by two H_1 -receptor blockers, diphenhydramine and pyrilamine ($5 \times 10^{-6} \text{M}$ each).

In conclusion, these studies show that in addition to its well established activity as an α -adrenergic blocking agent, tolazoline is a histaminergic agonist. The use of this classification to describe tolazoline may provide the perspective needed to understand most of its pharmacological properties including the vasodilatory effects underlying its clinical usefulness. Indeed, we have shown that its pressor activity in the anaesthetised rabbit is abolished by pyrilamine unmasking a depressor response to tolazoline which is completely blocked by metiamide¹⁴. Furthermore, in the light of our evidence, previous investigations using tolazoline may require some reinterpretation because of a failure to distinguish between the adrenergic blocking activity and the histaminergic components of its actions. This may be particularly true of experiments in which tolazoline was used as a tool to dissect the actions of other drugs or to understand the functions of the adrenergic nervous system. In such cases the results can be ambiguous or misleading since in some tissues the activation of histamine receptors produces biological effects opposite to those of adrenaline while in other instances histaminergic and adrenergic effects are similar. Finally, our findings provide the medicinal chemist with fresh

clues for the design of histamine agonists and blocking agents.

We thank Drs J. W. Black and M. E. Parsons for burimamide, Dr Lee Greene for metiamide and Ms Ann Savacool for statistical analysis.

Identification of novel high affinity opiate receptor binding in rat brain

SPECIFIC opiate receptor binding sites¹⁻³, occur in the brains of numerous vertebrates. In our initial studies⁴⁻⁶ binding seemed to involve a homogeneous population of receptors, although the biphasic degradation of receptor binding by trypsin and chymotrypsin suggested more than one site³. We have used ³H-naloxone and ³H-dihydromorphine of very high specific activity, and now report evidence for a new high affinity opiate-binding site in addition to the already reported binding site of lower affinity. The high and low affinity binding site may reflect interactions of opiates with two conformations of the opiate receptor which determine agonist and antagonist actions of the drugs.

Male Sprague-Dawley rats (ARS Sprague-Dawley, Madison Wisconsin, 180-220 g) were decapitated and their brains removed immediately. The cerebellum, which contains negligible binding¹, was excised and the remainder of the brain was placed immediately in the appropriate volume of iced standard Tris-HCl buffer (50 mM, pH 7.7 at 25°C) and homogenised with a Brinkmann Polytron for 60 s at setting 3. The homogenate was centrifuged for 20 min (49,000g, 0°C), the supernatant discarded, and pellets resuspended in the original volume of iced Tris-HCl buffer with a Brinkmann Polytron for 30 s at setting 3. Samples of 2 ml were then assayed with either ³H-naloxone (New England Nuclear Corp., 23.6 Ci mmol^{-1}) or ³H-dihydromorphine (New England Nuclear Corp., 53.6 Ci mmol^{-1}) at the stated concentrations and conditions, then filtered and counted as previously described⁵. Values are reported as stereospecific opiate binding⁵ and based on the means of triplicate determinations. All experiments were replicated at least three times. Values for the dissociation constants and number of binding sites were determined according to Klotz and Hunston⁷.

Scatchard plots of ³H-naloxone binding both in the presence and absence of sodium describe curves which can be resolved into two linear components with K_D values of 0.4 nM and 30 nM for high and low affinity binding respectively (Fig. 1a). Previously we reported that sodium increases the binding of ³H-naloxone and decreases the binding of ³H-dihydromorphine^{6,8}. When 100 mM sodium was included in the incubation medium, the number of apparent high affinity binding sites almost doubled, but the

Fig 1 Scatchard plots of ^3H -naloxone and ^3H -dihydromorphine binding in the presence and absence of NaCl. *a*, ^3H -naloxone Scatchard plot. 2-ml samples of brain homogenate (100 vol) were assayed in triplicate as described in the text, with various concentrations of ^3H -naloxone in the presence (\times) or absence (\bullet) of 100 mM NaCl and either (—) or (+) 3-hydroxy-N-allyl-morphinan at $0.1 \mu\text{M}$. *b*, ^3H -dihydromorphine Scatchard plot. 2-ml samples of brain homogenate (100 vol) were assayed in triplicate, as described in the text, with various concentrations of ^3H -dihydromorphine in the presence (\times) or absence (\bullet) of 100 mM NaCl and either (—) or (+) 3-hydroxy-N-allyl-morphinan at $0.1 \mu\text{M}$. All values for binding are stereospecific.

number of low affinity sites was unaffected and there was no significant effect on the dissociation constants. The increase in ^3H -naloxone binding elicited by sodium resembled our previous observations^{8,9}.

Biphasic Scatchard plots were also obtained for ^3H -dihydromorphine binding (Fig 1 *b*). In the absence of sodium, high affinity binding for ^3H -dihydromorphine had a dissociation constant of about 0.3 nM, and low affinity binding exhibited a dissociation constant of about 3 nM. Sodium (100 nM) virtually abolished the high affinity binding of ^3H -dihydromorphine but had no apparent effect on the low affinity binding sites. Thus the effects of sodium on the binding of opiate agonists and antagonists are exerted predominantly on high affinity binding components.

The affinity of a ligand for its receptor is determined in part by its rate of dissociation from the receptor so that one would predict a slower dissociation rate for the novel high affinity binding site described here than was obtained for the lower affinity binding site reported previously⁴. Accordingly, after labelling the receptor with low concentrations (1 nM) of ^3H -naloxone we measured its dissociation from the receptor. Following the standard incubation the homogenate was centrifuged (49,000g for 20 min) and the pellet suspended in 10 times the original volume with $1 \mu\text{M}$ unlabelled naloxone incubated for various intervals at 0°C , filtered and counted. The half-life for dissociation of

naloxone was 30 min in contrast to a 5-min half-life reported at this temperature with higher concentrations of ^3H -naloxone labelling the 'low' affinity binding site⁴. The slower dissociation rate of lower concentrations of ^3H -naloxone is consistent with labelling of a novel binding site with high affinity.

In this study, using ^3H -naloxone and ^3H -dihydromorphine of high specific activities, we have detected a new opiate binding component with 100 times the affinity of ^3H -naloxone-binding sites described earlier^{4,5}. This high affinity binding, detected by using low concentrations of ^3H -opiates and ^3H -opiate antagonists, displays the same pharmacological specificity as binding using higher ^3H -drug concentrations^{1,4}.

What might be the functional significance of the high and low affinity opiate binding sites? We propose that they represent binding of opiates to two distinct conformations of the opiate receptor described recently⁸⁻¹⁰. The ability of sodium to increase binding of opiate antagonists and to decrease the binding of opiate agonists to the same extent implies that the opiate receptor exists in two forms. Antagonists have greater affinity for the antagonist-sodium form of the receptor while agonists bind preferentially to the agonist-no sodium receptor state. Pharmacological actions such as analgesia occur only when a drug binds to the agonist state of the receptor so that antagonists block the effects of opiate analgesics by binding to the antagonist conformation of the receptor, reducing the number of agonist forms of the receptor. The data presented here suggest that the 'high affinity binding' of ^3H -naloxone involves the antagonist conformation of the receptor while low affinity ^3H -naloxone binding takes place to the agonist state of the receptor. Conversely, high affinity and low affinity ^3H -dihydromorphine binding respectively involve the agonist and antagonist states of the opiate receptor.

Fig 2 A model of opiate receptor function.

While binding to the agonist form of the receptor is impaired by sodium, binding to the antagonist form should be unimpaired or increased. ^3H -dihydromorphine binding to high affinity sites is greatly reduced by sodium while its binding to low affinity sites is unaffected, which confirms our suggestion that low affinity binding of ^3H -dihydromorphine involves the antagonist state of the receptor. Our inability to demonstrate a marked sodium-induced enhancement in low affinity ^3H -dihydromorphine binding and a reduction in low affinity ^3H -naloxone binding may be the result of difficulty in measuring binding at these high ligand concentrations because of the high nonspecific binding and the difficulty in separating the high and low affinity binding sites by Scatchard analysis⁷.

We reported that several protein modifying reagents which attack sulphhydryl, tryptophan and other residues selectively decrease receptor binding of opiate agonists at low concentrations which do not affect antagonist binding^{9,10}. These reagents seem to interfere with the interconversion of agonist and antagonist conformation of the opiate receptor so that it freezes in the antagonist con-

formation. If, as postulated here, high and low affinity binding of ^3H -dihydromorphine respectively involve agonist and antagonist states of the receptor, protein modifying reagents should selectively impair high affinity binding of ^3H -dihydromorphine with no effect on low affinity binding. To test this idea, we examined the influence of iodoacetamide on ^3H -dihydromorphine binding at concentrations that reduce agonist but not antagonist receptor binding. In confirmation of this prediction, iodoacetamide markedly lowered high affinity binding of ^3H -dihydromorphine with no effect on its low affinity binding.

In summary, high and low affinity binding to the opiate receptor may reflect discrete interactions with the two conformational states of the receptor that account for the pharmacological properties of agonists and antagonists. The two binding sites may provide a valuable tool to investigate opiate receptor conformations.

Prevention of the effects of fentanyl by immunological means

INVESTIGATIONS have demonstrated that the pharmacological effects of drugs such as digitalis¹ and paraoxon² can be altered by immunological means. To date, however, all reported attempts to antagonise immunologically the *in vivo* pharmacological effects of narcotic analgesics (such as morphine) have resulted only in mild attenuation or a partial delay in the onset of action³⁻⁵. To prevent immunologically the effect of a pharmacologically active molecule, sufficient amounts of specific antibodies must be present so that less than a threshold dose of the free drug remains after combination with the antibodies. Such a condition would be maximised with a drug which can be rendered highly immunogenic and which can exert its pharmacological effect at very low concentrations. We report that it is feasible to prevent the pharmacological effects of the potent narcotic analgesic fentanyl in experimental animals by both passive and active immunisation.

We have previously reported^{6,7} that high titres of antibodies of high specificity and affinity could be induced against the very potent synthetic narcotic analgesic, fentanyl. Fentanyl [N-(1-(2-phenethyl-4-piperidinyl) propionanilide)] has a spectrum of pharmacological effects similar to morphine, all of which can be antagonised by naloxone, however, fentanyl produces pronounced analgesia at 1/200 the dose of morphine.

Fentanyl, therefore, seemed to be a good candidate for investigating the neutralisation of the effects of an opiate-like drug by antibodies.

Antifentanyl antibodies were produced by immunisation of two rabbits with carboxyfentanyl [N-phenyl, N-4(1(β -phenethyl) piperidine succinamic acid)] conjugated to the protein carrier bovine gamma globulin (BGG). Conjugation was performed using 1-ethyl-3-(3-dimethylamino-propyl)-carbodiimide as previously described⁸, the conjugate containing 12 mol fentanyl per mol BGG. Immunisation was achieved by three bi-weekly subcutaneous injections of 2 mg conjugate in saline emulsified with an equal volume of Freund's complete adjuvant (FCA). The antigen binding capacity of the antisera produced was such that 0.25 μl serum could bind 0.005 μg and 0.0025 μg ^3H -fentanyl, respectively.

Table 1 Prevention of fentanyl analgesic effect by neutralisation of the drug *in vitro* and by passive and by active immunisation

Treatment	No. of mice	Hot plate end points (s \pm s.e.m.)	
		Before treatment	90 s after treatment
Neutralisation*			
Fentanyl+saline	5	9.8 \pm 0.99	> 60
Fentanyl+control serum	5	8.6 \pm 0.99	> 60
Fentanyl+immune serum	5	6.8 \pm 0.62	7.7 \pm 1.62
Passive immunisation†			
Control serum	5	7.0 \pm 0.57	> 60
Immune serum followed by fentanyl	5	7.4 \pm 0.75	7.8 \pm 1.12
Active immunisation‡			
Immunisation with fentanyl-BGG conjugate in FCA	15	8.0 \pm 0.49	18.8 \pm 5.6
Immunisation with FCA only	10	6.8 \pm 0.54	> 60

*Fentanyl was administered at a dose of 100 μg kg^{-1} in a total volume of 0.2 ml per 30 g mouse. Fentanyl was incubated with saline, control serum or immune serum for 10 min at room temperature before intravenous administration. Saline, control serum and immune serum, when injected alone to control mice, did not alter the end point.

†Mice were given 0.5 ml control serum or immune serum intravenously and challenged with 100 μg kg^{-1} fentanyl (0.2 ml per 30 g mouse) 30 min later. Control serum and immune serum, when injected alone to control mice, did not alter the end point.

‡Specific immunisation was performed with fentanyl-BGG conjugate in Freund's complete adjuvant (FCA), controls were immunised with saline in FCA. Injections were given intraperitoneally, twice at 2 weeks interval. Challenge with 100 μg kg^{-1} fentanyl in a total volume of 0.2 ml per 30 g mouse was performed 14 d after the last injection.

Assessment of the ability of rabbit antifentanyl antibodies to bind *in vitro* with the drug and to neutralise its analgesic effect was carried out as follows. An amount of fentanyl citrate equal to three times the ED_{50} dose ($3 \times 33 \mu\text{g}$ kg^{-1}) was preincubated for 10 min with 0.3 ml specific rabbit antisera, 0.3 ml of rabbit antiserum to tobacco mosaic protein, serving as control serum, or with 0.3 ml saline and then injected intravenously to NAMRU mice⁹. The mice were subsequently tested for analgesia by the hot plate technique of Eddy and Leimbach⁹ using their criteria for end point determinations. Each mouse was tested on the hot plate before, and 90 s after intravenous injection. The results of these experiments show that intravenous administration of 3ED_{50} of fentanyl, either in saline or preincubated with control serum, produced analgesia in 100% of the tested mice. In contrast, when 3ED_{50} of fentanyl were preincubated with specific rabbit antifentanyl serum the analgesic effect of fentanyl was dramatically reduced (Table 1). We then ascertained whether prevention of drug effects could be accomplished by passive immunisation *in vivo*. Two groups of mice were given intravenous injections of either 0.5 ml of the rabbit antifentanyl serum or 0.5 ml control serum, 30 min

Fig 1 Prevention of the effect of fentanyl in dogs *a*, *In vitro* neutralisation $5 \mu\text{g kg}^{-1}$ fentanyl were preincubated with 2 ml saline (\circ), 2 ml control globulins (Δ) or 2 ml antifentanyl globulins (\blacktriangle) for 10 min at 37°C . The mixtures were given intravenously to two dogs at zero time (\longrightarrow) *b*, Passive immunisation two dogs were injected intravenously with 2 ml saline (\circ), 2 ml control globulins (Δ) or 2 ml immune globulins (\blacktriangle) 30 min before challenge with $5 \mu\text{g kg}^{-1}$ fentanyl at zero time (\longrightarrow)

later each mouse was challenged intravenously with 3ED_{50} of fentanyl. Table 1 shows that the analgesic effect of fentanyl was prevented only in mice receiving specific rabbit antifentanyl serum, the remaining animals exhibited analgesia. To determine whether active immunisation of mice would alter the analgesic effect of fentanyl, we immunised two groups of mice, one group receiving two intraperitoneal injections, 14 d apart, of $250 \mu\text{g}$ fentanyl-BGG conjugate in 0.1 ml saline emulsified with equal volume of FCA, the second receiving two identical injections of saline emulsified with FCA. Ten days after the second injection all the animals were bled from the tail vein, sera were collected and titres of antifentanyl antibodies determined by the Farr assay¹⁰ as follows: various dilutions of pooled sera were incubated for 60 min at room temperature with $0.01 \mu\text{g}$ of internally labelled ^3H -fentanyl. The complex was precipitated at 50% saturation of ammonium sulphate, washed three times with 50% saturated ammonium sulphate, the precipitate taken up in 10 ml scintillation fluid and the radioactivity determined on the Nuclear Chicago Mark I scintillation counter. The fentanyl-BGG-immune sera had titres to the extent that 1 μl could bind $0.0075 \mu\text{g}$ ^3H -fentanyl. Four days after serum collection the mice were challenged intravenously with 3ED_{50} of fentanyl. Table 1 shows that active immunisation prevented the analgesic response in mice challenged with 3ED_{50} of fentanyl.

To determine whether drug effects other than analgesia could also be prevented by antifentanyl antibodies, we monitored systolic blood pressure, diastolic blood pressure, respiration rate and heart rate in dogs. Preliminary experiments with two dogs weighing approximately 10 kg each showed that the intravenous administration of $2.5 \mu\text{g kg}^{-1}$ fentanyl produced marked effects on the selected parameters. Two other dogs were anaesthetised with halothane, and maintained at a minimal stable level of anaesthesia with 1.5% halothane. Neutralisation of the effects of fentanyl was attempted by preincubation of $5 \mu\text{g kg}^{-1}$ fentanyl with 2 ml control globulins, antifentanyl globulins or saline, followed by intravenous administration of the various mixtures into each of the dogs. Figure 1*a* shows that all the effects of the drug were prevented by antifentanyl antibodies, whereas the effects of the drug were fully expressed

(even to the extent that breathing had to be assisted) in the controls.

Passive immunisation was then attempted by administering 2 ml of antifentanyl globulins to two mongrel dogs (10 kg body weight) and then challenging 30 min later with $5 \mu\text{g kg}^{-1}$ of fentanyl. Figure 1*b* shows that only the administration of antifentanyl globulins had the capacity to prevent the effects of the challenging dose of fentanyl. Previous administration of either saline or control globulins had no effect on subsequent fentanyl administration.

We thank Richard Martucci and Kevin Rivers for technical assistance.

Liver tryptophan pyrrolase activity and metabolism of brain 5-HT in rat

TRYPTOPHAN is the amino acid precursor of 5-hydroxytryptamine (5-HT) both peripherally and in the central nervous system, but the metabolism of tryptophan by way of the 5-HT pathway accounts for only 1% of urinary tryptophan metabolites¹. The major route of tryptophan metabolism starts with its conversion to formylkynurenine by tryptophan pyrrolase², and it has been suggested^{3,4} that depressive illness may be caused by the induction of liver tryptophan pyrrolase by plasma corticosteroids⁵, leading to decreased synthesis and turnover of 5-HT in the brain. We confirm the increase in activity of liver tryptophan pyrrolase produced by hydrocortisone and the decrease in activity by allopurinol reported by Curzon and Green². Hydrocortisone also increased the concentration of 'free' tryptophan in the serum. Although the concentration of 5-HT in the brain was unchanged, tryptophan and 5-hydroxyindole acetic acid (5-HIAA) concentrations in the brain were also increased. 'Free' and total tryptophan concentrations in the serum were reduced by allopurinol injection, but concentrations of tryptophan in the brain were unchanged. These results are not compatible with the theory that the induction of liver pyrrolase by hydrocortisone induces the symptoms of depression.

Male Sprague-Dawley rats (250–300 g) were housed at constant temperature under a 12 h light/12 h dark cycle. The effects of the injection of hydrocortisone (15 mg kg^{-1}) and allopurinol (20 mg kg^{-1}) on liver tryptophan pyrrolase activity were measured and related to changes in 'free' and total tryptophan concentrations in the serum, brain tryptophan, 5-HT and 5-HIAA concentrations (Table 1). Induction of the enzyme by hydrocortisone was maximal 3 h after injection¹. Total tryptophan concentrations in the serum remained

Table 1 Effect of hydrocortisone and allopurinol on pyrrolase activity and tryptophan metabolism

All animals were killed at approximately the same time of day to avoid the influence of the circadian variation of tryptophan, 5-HT and 5-HIAA in rat brain and serum. Total tryptophan in serum and brain was assayed by the method of Denckla and Dewey⁶, unbound tryptophan was assayed by the same method following equilibrium dialysis against Krebs-Ringer solution (pH 7.4). 5-HT was assayed by the method of Snyder *et al.*⁷, and 5-HIAA by the method of Giacalone and Valzelli⁸. Liver tryptophan pyrrolase activity was estimated by the method of Knox and Auerbach⁹.

* Significance at $P < 0.01$ level, [†] significance at $P < 0.001$ level.

Means \pm s.e. are shown. Numbers of animals per group in parentheses.

unchanged but concentrations of 'free' tryptophan in the serum and brain tryptophan were significantly increased ($P < 0.001$). Brain 5-HT concentrations were unchanged but brain 5-HIAA concentrations were significantly increased ($P < 0.01$).

Liver tryptophan pyrrolase activity was significantly decreased ($P < 0.001$) by the injection of allopurinol (20 mg kg^{-1}) intraperitoneally. Concentrations of total tryptophan in the serum were simultaneously reduced by 60% and of 'free' tryptophan by 53%. The concentrations of tryptophan in the brain were also lowered.

When allopurinol and hydrocortisone were administered together the increased pyrrolase activity induced by hydrocortisone was reversed. No significant change in concentrations of tryptophan in the brain was measured but total and 'free' tryptophan in the serum were reduced by 60% and 30% respectively.

Corticosteroids have been shown to elevate free amino acids in the plasma as a result of protein breakdown in tissues other than the liver⁵, and to enhance synthesis of liver protein including the synthesis of liver tryptophan pyrrolase⁹. Concentrations of total and 'free' tryptophan in the plasma may therefore be expected to depend on the balance of these systems. Knott and Curzon⁹ have shown that the concentrations of tryptophan in the brain are correlated with concentrations of 'free' tryptophan in the plasma. Our results agree with this latter correlation since the concentrations both of 'free' tryptophan in the serum and of tryptophan in the brain were increased after hydrocortisone injection but total tryptophan concentrations remained unchanged. Since the concentrations of tryptophan in the brain are below the K_m for tryptophan hydroxylase¹⁰ it is not surprising that the increased concentrations of brain tryptophan led to an increased turnover of 5-HT in the brain.

The hypothesis developed by Curzon³ maintained that low concentrations of 5-HT in the brain were related to increased pyrrolase activity which in turn was caused by high corticosteroid concentrations. This hypothesis depends on the assumption that the induction of liver pyrrolase by corticosteroids results in a decreased availability of tryptophan for conversion to 5-HT in the brain. The effects of hydrocortisone demonstrated in these experiments make this theory untenable, although the possibility that corticosteroids may participate in altering the metabolism of 5-HT in the brain cannot be discounted, particularly in light of recent evidence which suggests the presence of a pyrrolase enzyme in the brain¹¹.

It is also possible that, as suggested by Curzon, long term activation of pyrrolase could cause a functional deficiency of pyridoxal in the brain, or that elevated levels of tryptophan

metabolites formed on the pyrrolase pathway could have secondary effects on 5-HT levels¹².

Increased UDP kinase activity in rat and human hepatomas

PREVIOUS work¹⁻⁴, (carried out in this laboratory with the molecular correlation concept as a conceptual and experimental approach resulted in an insight into the biochemical strategy of the cancer cell) much of it conducted with a model system of hepatomas of very different growth rates⁵, has revealed a gradually emerging metabolic imbalance that is linked with the increase in tumour growth rate^{1,4,6-12}. Such biochemical alterations were manifested in progressive changes in the activities of opposing and competing key enzymes and opposing and competing metabolic pathways that correlated closely with tumour growth rate. These alterations in gene expression that seem to be linked with the increase in the expression of malignancy were manifested in increases in the activities of key glycolytic, pyrimidine and DNA synthesising enzymes^{4,7-12}. Concurrently, there were progressive decreases in the activities of the key enzymes of gluconeogenesis, pyrimidine catabolism and the urea cycle^{4,7,8,10,12}. In addition to this 'malignancy-linked' (growth-rate-linked) metabolic imbalance, we now show that the reprogramming of gene expression in cancer cells entails 'transformation-linked' alterations that are present in all hepatomas irrespective of growth rate or differentiation.

Our investigations on the UTP-synthesising enzyme, UDP kinase (nucleosidediphosphate kinase, ATP UDP phosphotransferase, EC 2 7 4 6) were undertaken because in the hepatomas of different growth rates the capacity of certain key enzymes involved in the biosynthesis of UDP increased in parallel with cell proliferation rate¹³⁻¹⁵. Concurrently, utilisation of UDP was potentiated by an enhanced activity of ribonucleoside-diphosphate reductase (EC 1 17 4 1)⁹. Quantitatively smaller increases were also observed in differentiating and regenerating liver^{11,13} (for reviews see refs 11 and 14-16). Since the reductase and the UDP kinase compete for the UDP pool, their strategic metabolic positioning suggests that a critical imbalance in the reprogramming of gene expression may be present in the spectrum of hepatomas of different growth rates (Fig 1). Our studies with various hepatomas of vastly different growth rates and differentiation showed that specific activities of UDP kinase were markedly increased in all neoplasms irrespective of tumour proliferation rate or degree of differentiation. This increased potential for UTP biosynthesis should provide a mechanism by which the cancer cell can adjust the utilisation of UDP for RNA and deoxyribonucleotide biosynthesis for subsequent formation of DNA.

Male Buffalo and ACI/N rats were maintained as described previously^{4,7}. Preparation of regenerating liver, studies on developing animals, killing of rats and excision of livers and tumours were as reported elsewhere^{4,7,12}. The growth rates of the various hepatoma lines ranged from 2 weeks to 11.5 months, measured by the time required for the tumours to reach a diameter of 1.5 cm.

Fig 1 UDP metabolism. This simplified schematic diagram indicates the strategic position of UDP in pyrimidine, RNA and DNA metabolism. The role of the four enzymes involved in UDP production and utilisation is noteworthy. For further details on the behaviour and interrelationships of the key enzymes and metabolic pathways in liver neoplasia, see review by Weber⁴.

Kinetic studies were carried out to ensure proportionality of UDP kinase activity with amount of enzyme added. A standard enzyme assay system was developed that was adapted to the kinetic conditions of the rat liver and hepatoma systems. UDP kinase specific activity was expressed as μmol of substrate metabolised $\text{h}^{-1} \text{mg}^{-1}$ protein. The details of the assay and a comparison of the specific activity and protein content are given in Fig 2.

The kinetic characteristics of UDP kinase activity from crude enzyme preparations of rat liver and the rapidly growing hepatoma 3924A were similar. The pH optima were broad,

Fig 2 Increased uridine-5'-diphosphate kinase (UDP kinase) activity in rat hepatomas of different growth rates. One per cent homogenates (w/v) were prepared at 4°C from liver and tumour tissues in 0.15 M KCl, pH 7.4, which were made 5 mM dithioerythritol (DTE) after protein determination. Supernatant fluids (100,000g) were used for the determination of UDP kinase activity as measured by the conversion of ^3H -UDP to ^3H -UTP. The incubation mixture contained in a total volume of 0.2 ml, 50 μmol of glycyl-glycine, pH 7.5, 7.5 μmol of MgCl_2 , 1.5 μmol of β -mercaptoethanol, 7.5 μmol of ATP (diNa), pH 7.4, 2.5 μmol of UDP, 1.5 μCi of uridine-5- ^3H -5'-diphosphate ammonium salt (19.6 Ci mmol^{-1}), and 2 μl of a 1:4 dilution of 1% supernatant fluid. Enzymatic activity was determined by withdrawing three 30- μl samples at 2 min intervals and spotting directly on PEI-cellulose plates (Brinkmann), activated with 10% NaCl, at 65°C (hot air blower). The PEI-cellulose plates were washed for 10 min in 500 ml of anhydrous methanol and air dried. The product of the reaction (UTP) was separated from the substrate (UDP) chromatographically with 4.0 M HCOONa , pH 3.4, in glass rectangular tanks. No nucleoside-diphosphate (EC 3.6.1.6) activity was detected under these conditions. In this system the UTP spot was located (at the origin) with ultraviolet light, marked with a soft lead pencil, cut out with scissors and placed in counting vials with 10 ml of scintillation fluid (0.03% *p*-bis (2,5-phenyloxazolyl) benzene and 5% 2,5-diphenyloxazole in toluene from New England Nuclear Corp). ^3H -UTP was determined in a Packard Tri-carb (Model 3390) liquid scintillation spectrometer. Protein concentration was assayed by the Folin method of Lowry *et al*¹³, using recrystallised bovine serum albumin as a standard. One unit of UDP kinase activity will produce 1 μmol of UTP in 1 h at 37°C and pH 7.4. Specific activity was expressed as units per mg protein. UDP kinase activities of the hepatomas are compared with corresponding control liver values. The UDP kinase activity of the normal liver was 444 ± 9 μmol per h per mg protein. The data are means \pm s.e. of four or more animals in each group and the results are plotted as percentages of corresponding control liver values. The protein content was calculated as mg protein per gramme wet weight of tissue and it is also given in percentages. The measurement of growth rates of the individual hepatoma lines was discussed elsewhere⁴.

*Values statistically significantly different from the respective controls ($P < 0.05$).

ranging between 7.0 and 9.0. The apparent K_m values for UDP, ATP and MgCl_2 at pH 7.4 and 37°C were 0.5, 3.0 and 3.0 mM, respectively.

UDP kinase specific activities were markedly increased in all neoplasms irrespective of tumour growth rate or degree of differentiation. The specific activities in the slowly growing hepatomas 9618A, 20, 66 and 16 were 2.4, 3.9, 1.7 and 3.0 times greater, respectively, than those in the corresponding normal rat livers. In hepatomas of medium growth rates 47C, 8999, 7787, 44 and 7800 the activities were 2.2, 1.9, 1.9, 1.9 and

3.1 times higher than those in normal liver. In the rapidly growing neoplasms 7777, 3924A, 9618A2 and 3683, activities were 2.7, 1.8, 2.0 and 2.9 times greater, respectively, than those of normal liver.

In the 24-h regenerating liver, UDP kinase activity was similar to that in liver of sham-operated control rats. Enzyme activity in the average cell of 6-d-old rat liver was in the same range as that of the normal rat (data not shown). Since increased UDP kinase activity was present in the hepatomas, but not in rapidly growing differentiating or regenerating liver, the higher activity of this UTP-synthesising enzyme seems to be specific to neoplastic transformation. This tentative conclusion was supported by studies on two primary human hepatomas. Using the histologically normal samples from the human host liver as controls, we observed that UDP kinase specific activity in the two human hepatomas was increased 2.3 and 4.9 times.

Our studies demonstrate a marked imbalance in hepatoma UDP utilisation. Whereas UDP kinase activity was increased in all hepatomas irrespective of the rate of cell proliferation (Fig. 2), the ribonucleoside-diphosphate reductase activity from the very low levels of the liver (less than 2 pmol per h per mg protein) increased markedly in parallel with tumour growth rate⁹. Thus, the regulatory mechanisms for gene expression are reprogrammed differently for these two UDP-utilising enzymes. The reductase activity, as it is increased in parallel with the growth rate, is linked with the different degrees in the expression of malignant properties. In contrast, the increased UDP kinase activity, as it is present in all hepatomas, even in the most slowly growing well differentiated neoplasms, seems to be linked with the neoplastic transformation *per se*.

Our demonstration of high UDP kinase activity in hepatomas, irrespective of the degree of malignancy, differentiation or growth rate, suggests that the reprogramming of gene expression in malignant transformation is linked with an increase in the expression of this UTP-synthesising enzyme activity. In this laboratory recently there were discovered four such transformation-linked increases in enzyme activities, and they all relate to an increased potential in the routing of precursors to strategic biosynthetic processes. Thus, the increase in the activities of glucose-6-phosphate dehydrogenase (EC 1.1.1.49) and transaldolase (EC 2.2.1.2) provides an increased potential for channelling glycolytic intermediates into pentose phosphate biosynthesis¹⁷. The third alteration observed in all hepatomas was an increase in amidophosphoribosyltransferase (EC 2.4.2.14) activity which should also result in an increased potential for purine and nucleic acid biosynthesis¹⁸. In turn, the greater UDP kinase activity reported here should provide an increased potential for RNA and DNA biosynthesis.

These increases in the activities of key enzymes of ribose-5-phosphate biosynthesis, purine production and the increase in UDP kinase activity indicate a reprogramming of gene expression that should confer selective biological advantages to the neoplastic cells.

Role of precursor 16S RNA in assembly of *E. coli* 30S ribosomes

RECONSTITUTION of bacterial ribosomes occurs *in vitro* in a system containing ribosomal components only¹, which suggests that ribosomes also form by self-assembly *in vivo*. This inference is reinforced by the fact that intermediary particles, containing a similar fraction of ribosomal proteins, are observed both *in vitro* and *in vivo*¹⁻³. The *in vitro* reconstitution process, however, requires a very high energy of activation, presumably to force the intermediates into a rare conformational state^{1,4}. This requirement is too high to be compatible with the rate of ribosome formation *in vivo*⁵. Furthermore, there is evidence that the rate-limiting step which leads to the accumulation of the precursor particles *in vivo* does not involve spontaneous conformational change of these particles⁶. Although all the information, therefore, required to construct a ribosome must be present in its components, it seems that cells use an additional mechanism to facilitate their assembly.

We report that reconstitution of 30S particles occurs *in vitro* with a much lower energy of activation if the precursor form of 16S RNA (p16S)⁷ is used in place of the mature RNA (m16S), and if the RNA is complemented with ribosomal proteins (r-proteins) extracted from nascent rather than from pre-existing ribosomes. We suggest that to facilitate ribosome assembly bacterial cells use a morphopoietic factor which recycles between precursor particles and completed ribosomes in concomitance with the maturation of rRNA.

The ionic conditions of Traub and Nomura⁵ were used both to dissociate and to reassociate ribonucleoprotein particles. A mixture of p16S and m16S RNA, differentially labelled with ³H- and ¹⁴C-uracil and obtained from particles sedimenting on a sucrose gradient at 25-30S, was incubated with increasing amounts of r-proteins extracted from total ribosomes. Incubation was carried out for various times both at 0°C and at 40°C to determine the temperature dependence of the reconstitution of 30S particles.

To obtain an efficient incorporation of rRNA into 30S particles a twofold excess of 30S proteins had to be used. In these conditions reconstitution of 30S particles occurred only at 40°C (Fig. 1a). At 0°C both p16S and m16S RNA formed particles sedimenting at 20-22S (Fig. 1b). Thus in the standard conditions of Traub and Nomura p16S RNA is no more efficient than m16S RNA in forming ribosomal subunits, confirming a recent observation⁸.

When the r-proteins/rRNA ratio in the incubation mixture was increased to a value greater than 3, some p16S RNA was incorporated into particles sedimenting at 30S even at 0°C. The amount of ³H-labelled 30S formed at 0°C did not increase with the time of incubation. Incorporation was the same when the mixture was analysed in sucrose gradients after an incubation of 2, 20 or 60 min, although it did increase with the amount of r-proteins added. At a protein/RNA ratio of 10 to 12, all p16S RNA was incorporated into 30S particles at 0°C and m16S RNA formed particles sedimenting at about 25-26S.

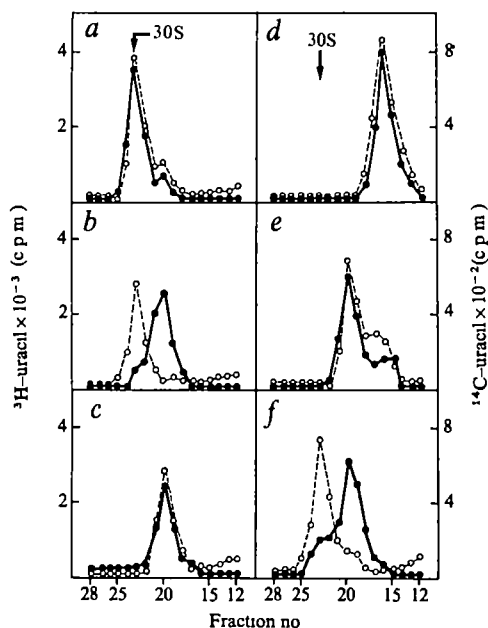

Fig 1 Reconstitution of 30S particles from p16S and m16S RNA in the presence of different amounts of r-proteins. ^3H -labelled p16S and ^{14}C -labelled m16S RNA were obtained from *E. coli* D10 cells growing in MS9 medium supplemented with 0.2% glucose and 0.5% casamino acids¹⁰. The culture (20 ml) was labelled with $1 \mu\text{Ci } ^{14}\text{C}$ -uracil (\bullet) for two generations and with $150 \mu\text{Ci } ^3\text{H}$ -uracil (\circ) for the last 2 min of growth. Cells were extracted at an A_{420} of 1.0 by pouring on to crushed ice, collected and lysed as previously described¹⁰. The lysate (1 ml in 10^{-2} M MgCl_2) was centrifuged on a sucrose gradient in 10^{-4} M MgCl_2 for 7.5 h in an SB238 International rotor at 40,000 r.p.m. The 30S peak was localised by counting an aliquot of each gradient fraction. Fractions containing material sedimenting from 25 to 30S were pooled and mixed with an equal volume of 8 M urea, 6 M LiCl. After 24 h the RNA was pelleted by centrifugation and redissolved in 0.3 M KCl, 20 mM Tris-HCl (pH 7.6), 2 mM MgCl_2 , 6 mM β mercaptoethanol and dialysed against the same buffer. An aliquot of RNA was precipitated with ethanol, redissolved in 1% sodium dodecyl sulphate and analysed using polyacrylamide gel electrophoresis as described previously⁹. The majority (90%) of the ^3H -labelled RNA (p16S) moved as a single sharp peak 6–8% slower than the ^{14}C -labelled RNA (m16S). Ribosomal proteins were extracted by the same LiCl-urea treatment both from total ribosomes and from native subunits and 70S particles. In the first case a crude extract of alumina ground cells was layered on top of a 5 ml sucrose gradient in 10^{-2} M MgCl_2 , and centrifuged long enough to pellet all ribosomal particles including native subunits and their precursors. In the second case, native subunits and 70S ribosomes were displayed on a regular sucrose gradient in 10^{-2} M MgCl_2 , localised by the A_{260} absorbance and collected by pelleting from the corresponding fractions. The pellets were resuspended in 4 M urea, 3 M LiCl, and 24 h later RNA was removed by centrifugation and supernatants were dialysed against 1 M KCl, 20 mM Tris-HCl (pH 7.6), 20 mM MgCl_2 , 6 mM β mercaptoethanol. To prepare the reconstitution mixture a sample of the RNA preparation was mixed at 0°C with the volume of protein preparation required to obtain the desired r-protein/rRNA ratio. KCl concentration was then reduced to a final value of 0.3 M by adding the appropriate volume of a buffer containing 20 mM Tris-HCl (pH 7.6), 20 mM MgCl_2 and 6 mM β mercaptoethanol. The relative amounts of RNA and protein were calculated from the volume of culture from which they had been obtained. After incubation at the temperature and for the time indicated below, the reconstitution mixtures were centrifuged on sucrose gradients in 10^{-3} M KCl, 10^{-2} M Tris-HCl (pH 7.6) for 7 h at 40,000 r.p.m. to display 30S particles and reconstitution intermediates formed. *a*, Protein from total ribosomes added in a ratio of 2.1 with RNA, incubated at 40°C for 20 min, *b*, as *a* but incubated at 0°C for 60 min, *c*, protein from total ribosomes added in a ratio of 12.1, incubated at 0°C for 5 min, *d*, protein from 70S ribosomes in a ratio of 4.1, incubated at 0°C for 5 min, *e*, protein from 70S ribosomes in a ratio of 30.1, incubated at 0°C for 5 min, *f*, protein from native subunits in a ratio of 4.1, incubated at 0°C for 5 min. The direction of sedimentation was from right to left.

(Fig 1c) ^{14}C -labelled 30S particles containing m16S RNA appeared at 0°C only at a protein/RNA ratio of about 30.

^3H -labelled 30S particles formed *in vitro* at 0°C starting from p16S RNA were capable of responding to T4 specific messenger RNA by entering polyribosomes when incubated in conditions for protein synthesis (data not shown, for detail on the assay see refs 6 and 9). This response was observed even when the assay was run at a temperature as low as 18°C to avoid the exposure of reconstituted particles to 37°C . On the basis of their ability to respond to T4 messenger RNA together with their sedimentation properties, therefore, ^3H labelled reconstituted particles resembled native 30S subunit and differed from the ^{14}C -labelled intermediary complex formed in the same reconstitution mixture starting from m16S RNA.

p16S RNA can thus form 30S particles in the cold more efficiently than m16S RNA. Several possibilities may be advanced to suggest why this does not happen in the presence of stoichiometric amounts of r-proteins but only in the presence of a large excess. Some ribosomal proteins could be partially inactivated during the extraction procedure. At 40°C , however, a protein/RNA ratio of 2–3 was sufficient to convert all rRNA into 30S particles, indicating that the putative inactivation was reversed by heating. Preheating r-proteins at 40°C before mixing with the RNA, however, did not relieve the high ratio requirement for the reconstitution of 30S at 0°C . Second at 0°C the 20–22S complex formed could have a much lower affinity for the missing proteins than at 40°C . When the RNA concentration was also increased twenty-five to thirtyfold that is, when stoichiometric amounts of RNA and protein were incubated at a very high concentration, no 30S formation occurred.

Third, a factor present only on a minor fraction of ribosome could lower the energy of activation of 30S assembly, allowing it to occur rapidly at 0°C . To test this hypothesis, we extracted proteins from 70S ribosomes and from native ribosomal subunits separated by sedimentation on a sucrose gradient. The preparation of ribosomal subunits included ribosomal precursor particles. As shown in Fig 1d and e, proteins extracted from 70S ribosomes did not sustain the formation of 30S particles in the cold even at a protein/RNA ratio of 30. Complete incorporation of p16S RNA into 30S particles was instead obtained with proteins extracted from native subunits at a ratio of 4 (Fig 1f).

The assembly of 30S particles *in vitro* may therefore be facilitated by a factor which can be extracted with the proteins from newly formed or precursor ribosomal particles, but is absent from most mature ribosomes. The factor acts preferentially on the precursor form of 16S RNA and, in the conventional reconstitution system used here, does not seem to function catalytically, but to be used up by the assembly reaction.

We propose that in the cell a factor exists which has the role of lowering the energy of activation required to convert precursor particles into 30S subunits. Because of its higher affinity for p16S than for m16S RNA, the factor would be released from completed ribosomes only after rRNA is matured. rRNA maturation, on the other hand, probably occurs in polyribosomes (ref 9 and G.M., E.T., C.P. and F.A., unpublished). Thus the recycling of the morphopoietic factor, and therefore the completion of nascent ribosomes, would be subordinated to the entry of previously formed particles into the pool of functioning ribosomes.

This work was supported by grants from Italian CNR and from NATO. We thank Dr D. Hayes for discussions and Dr I. Brody for reading the manuscript.

Hybridisation of Dane particle DNA with the free plasma DNA of hepatitis carriers

PLASMA of hepatitis B patients and antigen carriers contains a high concentration of spherical and filamentous particles (HBsAg), about 20 nm in diameter and without evidence of nucleic acid. There are also a relatively few spherical particles, 42 nm in diameter with a 28 nm core, first described by Dane *et al*¹. Dane particles contain a unique deoxyribonucleic acid² and a DNA polymerase³ capable of synthesising DNA so they are considered to be a leading candidate for a human hepatitis B virus. Double stranded DNA of unique base composition has been isolated from the naked intranuclear particle of hepatocytes of human hepatitis liver⁵. The large quantity of HBsAg, resembling defective virus, in the plasma of carriers prompted us to investigate a possibility that there may exist free or 'unassembled' DNA corresponding to the empty particles in these plasmas. The presence of both free DNA and empty particles could result from faulty assembly of a virus. We report here the presence of free DNA in HBsAg positive plasma and this free DNA showed homology with radiolabelled Dane particle DNA by molecular hybridisation.

Plasmas from commercial donors were screened by radioimmunoassays for HBsAg according to Ling *et al*⁵. In a typical procedure for DNA isolation, about 50 ml of plasma were dialysed against Tris buffer (0.01 M Tris-HCl, pH 8.25, 0.1 M NaCl) containing 0.01% diethylpyrocarbonate. Solid caesium chloride was added to the dialysed plasma to an average density of about 1.65, and the solution was then centrifuged in six buckets of a Spinco SW41 rotor at 35,000 r.p.m. for 67 h at 22°C. Because of the large amount of serum protein present in the sample, absorbance readings of the collected fractions were high and generally did not reveal separation of components. Occasionally, however, a small peak of absorbance at 260 nm appeared above the high background around a density of 1.7.

Fig 1 a, Isopycnic centrifugation of plasma in CsCl, b, the second CsCl centrifugation of the combined fractions around the density of 1.7 in a

(Fig 1a) Fractions around this density, regardless of the presence of an absorbance peak or not, were combined and dialysed against the same buffer. One or two recentrifugations of the sample in CsCl revealed DNA, if present, at a density of 1.698. The absorbance profile of a final centrifugation from a DNA-positive sample is shown in Fig 1b. The DNA showed a density of 1.423 in Cs_2SO_4 , $S_{20,w}$ values ranging from 10 to 22, and a T_m of 72°C in phosphate buffer (0.01 M, pH 7.15, 1 mM EDTA). The DNA appeared to be composed of linear double stranded molecules of about 2–3 μm . Details of the characterisation of this DNA will be described elsewhere.

Synthesis and isolation of 3H -thymidine labelled DNA from Dane particles were carried out as previously described³. Because of the minute quantity of DNA recovered from Dane particles, specific activities of the radiolabelled DNA could not be estimated. Hybridisation of the radioactive DNA and the plasma DNA was done according to a published method⁶ with the following modifications. About 2,500 c.p.m. of 3H -thymidine labelled DNA from Dane particles, and the non-radioactive

Table 1 Hybridisation between free DNA of plasma and 3H -DNA of Dane particles

Plasma	No of samples	No of DNA-positive sample	No of DNA-positive sample hybridised	No of positive hybridisation
HBsAg positive	21	21*	5	5†
HBsAg negative	21	2	2	2

* In a DNA-positive sample, A_{260} readings of the collected fractions from a 50 ml plasma were at least 0.01 above the background after the second CsCl centrifugation.

† In a positive hybridisation 1 μg of DNA protected more than 50% of the radio labelled Dane particle DNA from S1 nuclease digestion. Details of hybridisation conditions are described in the text.

plasma DNA were denatured, separately, with NaOH at pH 13 for 60 min at 37°C. Both DNA samples were then neutralised with HCl and incubated together in 1 \times SSC in a total volume of 130 μl for 4 h at 68°C. The quantity of cold DNA varied from 0.1 to 1.0 μg , estimated from spectrophotometric absorption where 24 A_{260} units were equivalent to 1 mg. After incubation, unhybridised, single-stranded DNA was digested with 1,000 units of S1 nuclease (Seikagaku Kogyo, Japan) for 2 h at 37°C. Calf thymus DNA (50 μg) was then added as a carrier and the reaction mixture was pipetted on 3 mm paper for washings in TCA according to Mans and Novelli⁷. Radioactivity was determined in a Beckman scintillation spectrometer. Negative controls in which cold DNA was omitted from hybridisation, served as the background of self-annealing which averaged about 10–15% of the input radioactivity. The value of 100% hybridisation was provided from reaction mixtures treated identically except that no S1 nuclease was used. DNA from human diploid cells (WI 38) and human liver tissue was isolated according to a published procedure⁸. Salmon sperm DNA and calf thymus DNA were purchased from the Sigma Chemical Company. These four DNA preparations were sonicated to give sizes comparable to plasma DNA with a $S_{20,w}$ range of 10–25.

It was evident from the results of hybridisation (Fig 2) that the DNA isolated from HBsAg positive plasma by isopycnic banding in CsCl possessed homology with the radioactive Dane particle DNA. Similar results in hybridisation were obtained with DNA after further purification by phenol extraction and alcohol precipitation. DNA from human liver, WI 38 cells, salmon sperm and calf thymus showed no evidences of homology. In the experimental conditions used, the C_0t_1 of the plasma DNA was estimated to be about $9 \times 10^{-2} \text{ mol s}^{-1}$. This value was considerably higher than that of a theoretical value of hybridisation (5×10^{-3}) between Dane particle DNA having a molecular weight of 1.6×10^6 with complexity of 2,600 nucleotide pairs¹⁰. This difference in observed and calculated C_0t_1 values could be due to two reasons. First, the hybridisation studies

Fig 2 Molecular hybridisation of plasma and heterologous DNA with ^3H -DNA of Dane particles (●), HBsAg plasma DNA, ▲, salmon sperm DNA, ■, WI 38 DNA, ○, human liver DNA

were conducted with molecules ($S_{20,w}$ of 10 to 22) much larger than small fragments of 400 to 500 nucleotides used to calculate the complexity of DNA from C_0t_1 values⁹. Thus the slower kinetics of reassociation with larger molecules would increase the C_0t_1 value¹⁰. Second, DNA not related to Dane particles, if present in the plasma DNA, would increase C_0t_1 . Further studies will be necessary to establish the full extent of homology between the DNA from plasma and the DNA produced by Dane particle polymerase.

Having found free DNA in a few plasmas from HBsAg carriers, we undertook a survey of 42 plasmas with regard to the presence or absence of free DNA and the ability of the DNA, if present, to hybridise with Dane particle DNA. The results of the study are shown in Table 1. In all of the 21 HBsAg positive plasmas examined, we found detectable amounts of free DNA with a recovered quantity equivalent to about 0.1–1 $\mu\text{g ml}^{-1}$ of plasma. Five of these twenty-one DNA preparations were selected randomly and were found hybridisable to ^3H -DNA of Dane particles. In the group of HBsAg negative samples we found the majority of samples (19/21) negative in free DNA in that no detectable absorbancy was found upon purifying the 1.7 density regions. Two of the samples, however, showed the presence of free DNA, and this DNA showed positive hybridisations with Dane particle DNA. The significance of this observation is not clear at this time, as we do not know whether free DNA in plasma is of host or viral origin. Further studies of these two plasmas are underway to assess fully the possible presence of HBsAg, undetectable with the methods employed.

The average length of the plasma DNA in electron micrographs was estimated to be 2–3 μm , equivalent to a molecular weight of 4×10^6 – 5×10^6 . In some plasmas, the DNA concentration was the order of 1 $\mu\text{g ml}^{-1}$, equivalent to 10^{10} molecules ml^{-1} . By comparison, a HBsAg concentration of 100 $\mu\text{g ml}^{-1}$ in the plasma could give 3×10^{13} particles ml^{-1} , based on a

molecular weight of 2×10^6 daltons per particle. The length of DNA was longer than that of the circular genome of Dane particle DNA (0.78 μm). We have observed rolling circles in electron micrographs of the DNA isolated from Dane particles actively synthesising DNA (ref. 3). These rolling circles¹¹ with different lengths of linear segments would represent progeny DNA in polymeric forms. Although we found considerable homology between the DNA in plasma and in Dane particles, it is yet to be proven that the plasma DNA contains homology equivalent to one or more copies of the Dane particle genome.

The Dane particle is a leading candidate for the hepatitis B infectious agent, based on the findings that they contain a unique DNA primed with a DNA polymerase and are found in infectious plasmas of HBsAg carriers. In spite of the routine screening of blood donors with sensitive HBsAg immunological procedures, only about half of the cases of hepatitis B associated with blood transfusion seem to be related to the presence of HBsAg or antibody in donor blood, as revealed by these methods. The findings in this report on the presence of free DNA having homology to the DNA of Dane particles suggests the possibility of using molecular hybridisation in conjunction with immunological techniques for assessing potential infectivity of blood plasmas.

We thank Dr T. Kakefuda for electron microscopic studies of DNA, Dr W. Holleman for analytical centrifugation studies and W. Schulze for technical assistance.

Errata

IN the article "Flow near an oscillating cylinder in dilute viscoelastic fluid" by C. Chang and W. R. Schowalter (*Nature*, **252**, 686, 1974), Figs 2b and 3b should be interchanged.

IN the article "Ambisonic reproduction of directionality in surround-sound systems" by P. B. Fellgett (*Nature*, **252**, 534, 1974) the following corrections are necessary: Page 537 line 6, for π read 2π , line 9, for hyper-spheres read elliptic spaces, in ref. 3 for 189 read 1892 (date), in Fig 2c the right-hand side of the CBS pan locus should be solid not dashed, to show that it is at the front (not the rear) of the sphere.

IN the article by A. I. Cunningham (*Nature*, **252**, 749, 1974) the title should read "Large numbers of cells in normal mice produce antibody against components of isologous erythrocytes" and not as printed.

reviews

In January 1972 a study group of psychologists and ethologists met in London to discuss the growth of competence, under the aegis of the Developmental Sciences Trust and the Ciba Foundation. This book represents the fruits of their discussion; it comprises 16 papers presented either at the symposium or commissioned during its aftermath for inclusion in the published proceedings.

Most of the original papers have been revised in the light of comments made at the conference, and the editors have written introductory and concluding chapters. It is unusual, however, for such manoeuvres to transform a collection of individual papers on a common theme into a plausible book in which an identifiable argument is developed, and it must be said that *The Growth of Competence* has several of the characteristic flaws of the standard conference book. The most serious of these may be anticipated: the word 'competence' has such wide vernacular use that it comes as no surprise to discover between the book's covers almost as many definitions of its central concept as there are contributors. And even though this state of affairs may arise from the nature of the concept rather than from lexicographical laxness on the part of the authors, its

Competence in many forms

John N. Nicholson

The Growth of Competence. (Proceedings of a DST Study Group.) Edited by Kevin Connolly and Jerome Bruner. Pp. xii+327. (Academic: London and New York, September 1974.) £6.80; \$17.50.

effect on the book may be imagined. There are, moreover, a number of chapters which can with charity be described as lightweight. They neither include material interesting in its own right nor contribute to the argument which, in spite of the handicap mentioned above, is developed in the book; they are presumably included in deference to the book's function as a document of record.

These shortcomings are particularly regrettable in view of the book's praiseworthy intentions and the admirable quality of some of the contributions. It sets out to describe competence; to place it in an evolutionary context (a wide-ranging chapter by Bruner); to exemplify its development in a number of areas, including infants'

relationships with their mothers and their peers, skills (a detailed description of Elliott and Connolly's pioneering analysis of manual skills in normal and cerebral palsied children), language acquisition and personality; and to point out the practical applications of the experiments discussed and theoretical issues raised.

The book's central argument is carried forward by those contributors who follow Bruner in likening the growth of competence to the development of skills, which he regards as an hierarchically organised repertoire of sub-routines. This analogy is pushed furthest by Susan Carey in a provocative chapter on the development of cognitive competence, based on her penetrating reanalysis of the conservation problem. But in the end the book cannot escape the limitations of its genre. Most of the experimental work has been described elsewhere; it is unlikely therefore to become mandatory reading amongst developmental psychologists. Educationalists may welcome the discussion of the efficacy of schools as socialising agents in contemporary society, but they will find little cheer in the editors' pessimistic view of the contribution psychologists have thus far been able to make towards the solution of such problems. □

The subject is fascinating. How is it that the principal area of technological rivalry between the two super-powers could within two years become the main field of cooperation in advanced projects? What shifts in foreign policy, in the scientific climate, even in personalities, mediated so radical a 'thaw'? Alas, one is not going to get more than a few hints from this book.

Was the untimely death of Dr Hugh Dryden, NASA's chief negotiator during the difficult early 1960s a significant setback? Did the 1964 Committee on Space Research (COSPAR) agreement on planetary contamination standards mark the first visible breakthrough of reason over rivalry (as was then widely reported)? There is no assessment of the first point and the second is not mentioned.

Disappointment with the book at first prompts the judgement that it is quite irrelevant. It is not; it is just biased. The book has apparently been developed through a series of studies by a team of authors drawing on a privileged

archive at the Center for Advanced International Studies of the University of Miami (CIAS). It presents a digest of official, documentary evidence and American reportage (which are given equal validity) within the matrix of the authors' own commentary.

The whole thing is set rolling in a predetermined direction with a 28-page

Detente in orbit

Angela Croome

U.S.-Soviet Cooperation in Space. By Dodd L. Harvey and Linda C. Ciccoritti. Pp. 350. (University of Miami: Florida, 1974.) \$8.95, paper; \$12.95, boards.

foreword by the United States Ambassador to Moscow in the mid-1960s, Foy D. Kohler, who is now luminary of CIAS. He discounts any possibility of an independent role or influence from Soviet scientists. He sees the entire pattern of cooperation as determined by Soviet political pressures. He may be right but his own professional

allegiance reduces any conviction and the material adduced suggests that there has been some careful selection to support his thesis. Nor does he acknowledge the equally overriding influence of American political postures on the turn of events during the 15-year period leading up to the 1972 Nixon-Brezhnev Agreement (the space cooperation programme was, significantly, a part of the overall detente agreement).

It is useful to have chapter and verse of the Dean Rusk papers (1962) which concluded that space had no military value for the United States and which suggested that the Soviet Union should appreciate this before adopting counter measures to a non-existent threat. That was a turning point.

The volume's 100-page bibliography would be invaluable if it could be consulted independently of the text. As it is, this 'analysis' is journalistic in approach but does not have the convenience of having been written by journalists. □

Magnetic models

Experiments on Simple Magnetic Model Systems: A Survey of their Experimental Status in the Light of Current Theories. (Taylor and Francis Monographs on Physics.) By L. J. de Jongh and A. R. Miedema. Pp. 269. (Taylor and Francis: London, August 1974.) £4.00.

Forty years elapsed between the discovery of superconductivity and the advent of a theoretical model describing the effect. A much greater period had passed at around the turn of the century when Weiss introduced the first theoretical model to account for another cooperative phenomenon, ferromagnetism. Since that time, increasingly complex and subtle models have been developed to allow more accurate calculations of thermodynamic quantities near phase transitions. The simplest models, restricted to one or two-dimensional crystal lattices, enable exact calculations and may seem to provide merely a playground for the theoretician. But those models now have, in fact, a relevance to the real world. Advancing technology has facilitated the identification and preparation of single crystals containing chains or layers of paramagnetic ions, isolated by distances of the order of tens of Angstroms, which, therefore, have a magnetic quasidimensionality of one or two.

A large part of this book is devoted to a review of the measured properties of such compounds and, although it is not easy reading, it provides an invaluable, and what must be an almost exhaustive, reference catalogue of these materials—the index to substances contains approximately 200 entries. The fitting of theory to experiment by judicious choice of the exchange constant is impressive in many cases.

There remain, however, some areas in which the available experimental analogues do not yet approximate closely enough to the models to confirm some theoretical predictions. An example of this is the two dimensional Heisenberg model, in which long-range order must be absent at finite temperatures: the expansion approach of the high temperature series suggests that the susceptibility will diverge at a finite temperature. The problem is resolved by identifying this temperature not with the normal phase transition but as a transition (the Stanley-Kaplan transition) to a state of infinite initial susceptibility with zero spontaneous magnetisation. Real materials deviate from the ideal because of the presence of anisotropy from single ion or dipolar contributions. Competing anisotropies can, however, be made to cancel, al-

though usually at a single temperature only. The best approach, therefore, seems to be to use a series of compounds in which the varying degree of deviation can be determined, then to extrapolate to the ideal. The authors believe that the evidence so obtained suggests that Stanley-Kaplan temperatures may exist.

In a final section a number of special topics are considered, including neutron diffraction and spin-wave theory.

This book, a reprint of *Advances in Physics*, 23, contains an elegant and concise review of the properties of the theoretical models of magnetic systems, and a comprehensive body of experimental data relevant to those models. As such, it is a useful addition to the library of the research worker in solid state magnetism.

W. O'Reilly

Insect behaviour

Experimental Analysis of Insect Behaviour. Edited by L. Barton Browne. Pp. viii+366. (Springer: Heidelberg, Berlin, New York, 1974.) \$15.40.

This volume originates from a symposium entitled "Experimental Analysis of Insect Behaviour" which formed part of the 14th International Congress of Entomology held in Canberra in 1972. The 25 contributions to the book include several not actually delivered at the symposium and some that are modified versions of the original papers. Most are written in the form of reviews, some of which are speculative,

emphasising particular areas of research, and some of which are of a more general nature.

Appropriately, because he addressed the closing plenary session of the Congress on "The emergence of behaviour", J. S. Kennedy's paper—"Changes of responsiveness in the patterning of behavioural sequences"—sets the tone of the volume by summarising his interpretation of flight and settling responses in *Aphis fabae*. The final paper, by Dingle, also deals with insect flight in the context of "The experimental analysis of migration and life history strategies in insects" and it is refreshing and encouraging to find many ecological concepts aired in such physiological company. Topics included in the intervening 23 papers include reproductive behaviour, feeding, several aspects of the insect nervous system and neural mechanisms, and hormone-mediated behaviour. Many of the papers are useful appraisals of recent work and concepts in the experimental analysis of insect behaviour, and it is convenient to have them so readily available.

Unfortunately, the editor has made little attempt to arrange the papers to present and develop an underlying theme, or to summarise the forward-looking approach that the symposium was, presumably, convened to stimulate. Indeed, the volume—reproduced from typescript—can only be considered as a 'book' in so far as it is bound between boards.

T. Lewis

Burial tombs of Tasmanian aborigines. From *Biogeography and Ecology in Tasmania*. (Monographiae Biologicae, vol. 25.) By W. D. Williams. Pp. 498+122 figs. (Junk: The Hague, 1974.) Dfl 140.

Physical Chemistry: An Advanced Treatise. Vol. VIA: *Kinetics of Gas Reactions*. Edited by William Jost. Pp. xx+507. (Academic: New York and London, November 1974.) \$43.00; £20.25.

THE editors of this series note in the Foreword that, because of the tremendous expansion in the development of techniques and principles of physical chemistry in recent years, most physical chemists "find it difficult to maintain an understanding of the entire field". This surely understates the problem, and I must admit, albeit sadly, that I find this difficulty even when restricted to my own chosen field of physical chemistry—kinetics—let alone the "entire field".

An advanced treatise should assume that the reader has at least a first degree level of knowledge, and this is certainly true of this volume. Indeed in some cases rather more is assumed of the reader.

The first chapter, on formal kinetics, by W. Jost makes an excellent start with a concise but clear survey of classical reaction kinetics, and leads on to a consideration of steady states, stability and, finally such topics as oscillating reactions; these latter topics have attracted much attention in the past decade. The next, short chapter, by C. F. Curtiss—A Survey of Kinetic Theory—is, in my opinion, too limited in scope and is at a level which surely assumes too much of a graduate student. It does not fit in happily with the rest of the volume. In the third chapter by H. Eyring and S. H. Lin, on potential energy surfaces, an account of the valence bond method is given and then surfaces for $H+H_2$, $Cl+Cl_2$ and $K+NaCl$ are considered in some detail. A final section on orbital symmetry in reaction kinetics does not blend well with the rest of the chapter and deserves a chapter of its own.

Chapter 4 is again short—E. E. Nikitin on the Theory of Energy Transfer in Molecular Collisions. The translation, though clear, is a little stilted and the treatment is too condensed; few readers will find it an easy introduction to this important topic. The final chapters constitute more than half this volume. Chapter 5 by J. P. Toennies is on molecular beam scattering experiments and considers elastic, inelastic and reactive collisions. This is a field that is progressing rapidly and this chapter presents a balanced and clear account of it. Chapter 6 by J. C. Polanyi and J. L. Schreiber on the dynamics of bimolecular reactions must, of necessity, cover some of the same ground as the earlier chapters. Such duplication as there is, however, is not serious, and the viewpoint is

somewhat different. Again, this chapter presents a clear account which most graduate students interested in kinetics will find valuable.

The chapter headings to the companion volume (VIB) on gas kinetics suggest that the two will fit together well. It is, however, sad to note how many important areas of gas kinetics will not be covered at all.

This book can be recommended for libraries, but at £20.25 it is hardly cheap and is unlikely to find itself on the shelves of all those 'physical chemists' for whom it was, no doubt, intended.

Gas works

Theory of Elementary Atomic and Molecular Processes in Gases. By E. E. Nikitin. Translated by M. J. Kearsley. Pp. xiii+472. (Clarendon: Oxford; Oxford University Press: London, August 1974.) £14.75.

THE author of this book is one of the world's leading authorities on the theory of rate processes, who has extensive and detailed research experience in many branches of the subject. This translation from the Russian version originally published in 1970 is, therefore, more than welcome. The emphasis rests on the theory of processes relevant to the chemical reactions discussed. The main body of the book makes reference to the literature published before the end of 1966, with an added appendix that includes brief reference to developments in the two or three years following that date.

Professor Nikitin presents a very wide, well integrated view of the subject as a whole, and thus the material in the various chapters of the book is well organised, with chapters following one another in a smooth fashion. The first chapter on the transition state method is presented in a very formal manner, going far beyond the statistical mechanical treatment normally found in standard books on kinetics. The following chapter, dealing with the transfer of translational motion to other forms of energy, especially to vibration, for which there is a large body of experimental data, and also to electronic energy in both atoms and diatomic molecules, is extensive and highly authoritative.

The chapter formally entitled "Unimolecular Reactions" may seem to be relatively limited, considering the scope of the subject, but it is a tight and formal approach. It follows well the chapter concerned with vibrational energy transfer and includes a section on surface crossing and "non-adiabatic

transitions". With that chapter one should also consider the following detailed treatment of the statistical theory of reactions. Similarly, the presentation of the diffusion theory of reactions, which regards chemical reactions as diffusion processes of representative points in phase space from regions corresponding to reactants to regions corresponding to products, is also highly relevant to the considerations of unimolecular reactions given in earlier chapters.

The dissociation of diatomic molecules and the reverse process of atomic recombination are dealt with more in terms of the types of results obtained from different theories than in terms of detailed developments of the leading theories. The appeal to experiment is very limited but the chapter is rich in the physical principles at issue in such processes. The basis of semi-empirical methods for bimolecular reactions is presented with particular clarity, and leads in due course to the more recent, *ab initio* calculations of Bruner and Conroy for the H_2 system.

Direct reactions and the dynamics of exchange reactions, of particular relevance to processes studied in molecular beams, are also dealt with fully. The appendix, clearly written after the main body of the book, is a useful brief résumé of the objectives of theories of chemical reactions. As the book is designed for post graduate chemists and physicists, the appendix could usefully be read first, especially as there is no general introduction.

Since the completion of the book, there has been a major development in the experimental study of many fundamental aspects of atomic reactions. Work on the collisional behaviour of atoms in specific electronic states, and various studies aimed towards the development of a framework within which context the relationship between electronic structure and atomic reactivity can be understood, comprise much of this development. These areas of research occupy little space, however, and it is to be hoped that the next edition will contain much more of that type of work, including Professor Nikitin's own theoretical researches.

For research workers concerned either with the theory or experiment of fundamental rate processes in gases, access to this book is barely a matter of choice but rather of basic necessity. Occasionally, the price of a book must be judged not only in relation to its size but to the quality of its content. This is such a book; it is hard to imagine a library without it, and it is to be hoped that research workers will consider that a classic work of this kind merits a place on their personal bookshelves.

D. Husain

obituary

Francis J. Weiss, the biochemist and economist concerned with developing food resources, died on January 21, at the age of 76.

Dr Weiss was born in Vienna, receiving doctorates in chemistry and economic statistics at the University there. He worked in the biochemistry institute of the University of Vienna until the Nazis occupied Austria in 1938, at which time he left for England. A year later, he went to the United States, where he was a consultant to the Board of Economic Warfare and the Sugar Research Foundation. In the fifties, he was a consultant on the staff of Senator Hubert H. Humphrey, studying chemical agriculture and new methods of processing grains. Later, he was a consultant to the International Cooperation Administration and the Department of Commerce. From 1959 to 1969, he was a specialist in the science and technology division of the Library of Congress.

Vladimir Aleksandrovich Fock, academician, and one of the leading theoretical physicists in the Soviet Union, died on December 27, 1974, five days after his 76th birthday.

Fock, who graduated from the University of Petrograd (now Lenin-

grad) in 1922, throughout his working life remained connected with this University, teaching and researching there. He also at various times worked at the State Institute of Optics, the Leningrad Institute of Physics and Technology, and the Institute of Physics of the Soviet Academy of Sciences. In 1932 he was elected a Corresponding Member, and in 1939 a full member of the Soviet Academy of Sciences. Fock's basic research was concerned with quantum mechanics, quantum electrodynamics, electromagnetic diffraction and radiowave propagation, the general theory of relativity, mathematics, and mathematical physics, in all of which fields he established new basic concepts. He is particularly associated with the establishment of the scalar relativistic wave equation for a particle with no spin in an electromagnetic field, which he derived independently of similar work by the Swedish physicist O. Klein (the 'Klein-Fock equation'). His name is also associated with spaces of an increasing number of dimensions ('Fock spaces'), which he used to obtain a quantum description of systems with a variable number of Bose particles. For his services to Soviet science, Fock was awarded the Order of Lenin (four

times), a Stalin Prize (now State Prize) in 1946 and a Lenin Prize in 1960. He was also a member of a number of foreign and international academies and learned societies.

Matthew W. Stirling, the distinguished archaeologist, died on January 23, at the age of 78.

An anthropologist and archaeologist associated with the Smithsonian Institution for more than 40 yr, Dr Stirling travelled widely in Central and South America, discovering "America's oldest dated work"—a stone monument bearing a date equivalent to 291 BC. He has headed many important expeditions in the Americas and in Europe, but will be known primarily for his contributions to middle American anthropology and archaeology. Under the auspices of both the Smithsonian and the National Geographic Society, Dr Stirling led the team of archaeologists who uncovered the La Venta, or Olmec, civilisation dating back more than 1,000 yr. Dr Stirling was born in California and graduated from the University there in 1920. He was affiliated with the Smithsonian from 1921 until his retirement in 1958. He also served as head of its bureau of American Ethnology from 1928 to 1947.

February 20, 1975

Did Dr Shah die in vain?

THREE years ago Dr V. H. Shah, a senior agronomist with the Indian Agricultural Research Institute (IARI), committed suicide in protest against the system prevailing in Indian agricultural research—and his was the third suicide of an agriculturalist in twelve years. His complaints, left in a letter to the director of IARI Dr Swaminathan, fell into two categories—first, that scientific results were being misrepresented to the extent that misleading and incorrect publicity was being disseminated; and second, that the career structure in agricultural research was being undermined by improper appointments. The failure of Dr Shah to be appointed to a professorship in agronomy was the immediate cause of his suicide, and in his letter he mentioned another appointment in agronomy which he also regarded as going to the wrong man.

Reaction was rapid. A committee of considerable eminence was established and reported in 1973. Since there were obviously more complaints in the air against the Indian Council for Agricultural Research (ICAR) than Dr Shah had spelt out, the committee investigated recruitment files and sent out questionnaires to a wide range of scientists.

To the accusation of scientific misrepresentation, the committee gave a mixed response. Dr Shah had named three specific cases, and in only one of the three did the committee go along with his accusation, although there were some sharp words on the way that advances in agricultural science were being publicised, and this criticism extended beyond the instances raised in the suicide note. The scientific issues have been rather extensively aired in *New Scientist* recently and need no further comment here.

The question of employment conditions and morale are, however, worth discussion. The committee unearthed much dissatisfaction and hard feeling within the agricultural community. This was directed at just about every aspect in their scientific life: appointments were said to be going to incompetents, library facilities were inadequate, there was too much power at headquarters, it was impossible to promote without there being a vacancy available (and competition for it) and equally impossible to get rid of incompetent workers. Perhaps most significantly, half the responses to the questionnaire on the question of what caused most difficulty in doing research blamed interference by supervisors.

The examining committee accepted the validity of much of this criticism. Indeed, the committee's own technical advisers themselves felt sufficiently strongly to write that the malaise which they had observed was not confined to ICAR, but "barring minor exceptions, pervaded the entire scientific and academic community of the

country. At root, it is greed for bureaucratic power and love of a comfortable life which afflicts this class. Juniors are intellectually as corrupt as seniors, and politicisation of academic and scientific life makes matters much worse."

Ironically the committee were not so impressed by two of the cases brought forward by Dr Shah himself. They found that the appointment which he had himself hoped to secure and which went to someone else was unobjectionable. And whilst they were critical of a second appointment made a few months earlier (Dr Shah had not applied for this post) there was considerable disagreement on whether a Ph.D in crop physiology plus ten years in agronomy was a suitable qualification for a post advertised as requiring a Ph.D in agronomy plus ten years' experience.

The almost obsessively narrow nature of this issue unfortunately provided a rather simple escape mechanism—better procedures in recruitment and promotion in ICAR. Unfortunate for two reasons—first because it is by no means clear that Indian science, already much stifled by its reverence for degrees, authority and seniority, needs even more rigid adherence to paper qualifications (a third of all who responded to the committee's questionnaire said that promotion should be based on seniority, without reference to merit). The best science doesn't always reveal itself to the best qualified. Second, because there is still no real sign that the Indian government sees more than administrative changes as necessary as a consequence of Dr Shah's suicide and this report. As the technical advisers bluntly put it, intellectual corruption exists at all levels; much more than changes in selection procedures are needed to eliminate it. The origins of this corruption are not difficult to find—they lie in the surfeit of bureaucracy, concentration of power at headquarters, a gross oversupply of graduates some of whom seem to acquire their degree only for matrimonial purposes, the shortage of money, the poor quality of technical help and the lack of diversity of opportunity within Indian science.

None of these problems is easily solved, but they are all potentially soluble. Mrs Gandhi, by being Minister for Science and Technology herself, is expressing a national faith that science and technology can still help India. She is in a powerful position to take bold steps to reduce mistrust and discontent amongst the scientific community, and she should take radical action.

We regret the poor quality of the paper on which last week's *Nature* was published. Continuity of paper supply has posed a continual problem for us, but we are doing everything possible to stabilise the situation.

Australopithecus africanus: discovered by accident

It is almost 50 years to the day that Nature published a report by Dr Raymond Dart describing the face, jaw and the brain case of a child belonging to what Dart described as "an extinct race of apes, intermediate between anthropoids and man". Nowadays, though chance and perspicacity still count in the search for hominid fossils, the scene has shifted from South to East Africa. The size of the cast has increased and both the extent of backstage support and the scale of the budget reflect the fact that hominid research has changed a good deal in the past half century. Bernard Wood reports.

THE child's skull which Dart called *Australopithecus africanus*, the southern ape, had been discovered by accident (*Nature*, 115, 195; 1925). It had been found in the rubble of a lime quarry at Taung, which is about 80 miles north of Kimberley in what was then Bechuanaland. It was fortunate that the remains of a fossil monkey had been recognised at the same quarry only a few months previously. The child's skull was in fact identified, and then passed on to Dart, by Professor Young, a geologist and one of those who had been alerted that the site was of potential interest.

The Taung child was not the first fossil hominid to be discovered; evidence had been found in the previous century at several sites in Europe and by Dubois in Indonesia. The Taung child was, however, much less 'man-like' than any of these other candidates for a relative or ancestor of man,

despite the fact that its young age tended to mask these non-human traits. Also it was the first specimen to be found in Africa, a continent that has since given up so much evidence to support Darwin's speculation that it was the cradle of mankind. In South Africa after Taung, Dart and Robert Broom, a noted palaeontologist, learnt of other cave sites in the dolomite of the Transvaal. Although no more hominid remains have been found at Taung, literally hundreds of specimens have been found at four other cave sites, and work has been resumed recently at three of these sites.

The other concentration of hominid fossil sites is in East Africa, and the circumstances could hardly be more different. The East African sites are all associated with the Rift Valley where hominid bones, and the evidence of hominid activity, are preserved in the silt of ancient lakes and streams, in-

stead of having been carried, washed or dropped into caves as in South Africa. The Rift Valley sites are only revealed to us now because earth movements have so distorted the landscape of several million years ago so that what were beds and shores of lakes are now thrust up and tilted so that they are exposed to erosion by water and wind.

An advantage of the location of these sites in sedimentary basins is that, with the help of palaeontologists and those skilled in palaeoenvironmental research, the life and landscape that the early hominids knew can be reconstructed. The intensity of diversification in contemporary animals and knowledge of the habitat are but two of the new dimensions that have been introduced into the interpretation of hominid remains. The stratigraphy of the sediments also enables the location of specific fossil finds within a large site to be placed in an order of occurrence. The tectonic activity that elevated and tilted the fossil sites was accompanied by volcanic eruptions, the products of which are suitable for isotope dating. These eruptions periodically covered the landscape and are now incorporated as layers of jam in the sedimentary sponge-cake. The dates of these strata provide bracketing ages for the fossils that lie in the intervening sediments. The history of the Earth's magnetic field can also be traced in the sediments which preserve the perturbations of the magnetic poles. When this information is combined with the results of the isotope dating techniques the East African site can be fitted into an absolute time scale enabling them to be placed in a historical context, one with another, and also with dateable sites elsewhere.

The problems of organising the team of research workers necessary for modern research into human origins, in inaccessible areas and often in a harsh climate, are probably no better illustrated than at East Rudolf in North Kenya.

This site, comprising sediments exposed in five main regions over an area of 2,000 square kilometres, was not found by accident. In July 1967 Richard Leakey was leading the Kenyan contingent of a multinational expedition that had been organised to explore the fossil potential of the Lower Omo Basin in southern Ethiopia. The area allotted to the Kenyan team turned out not to be as rich as that allocated to the French and US contingent who have since successfully jointly explored the exposed sediments known as the Shungura Formation on the west bank of the river. Leakey, however, realised that in flying from Nairobi to the fossil sites in Ethiopia he had flown over similar looking exposure

some several hundred kilometres further south on the north-east shore of Lake Rudolf. So, following a short aerial reconnaissance in 1967, the first East Rudolf Expedition was mounted by Richard Leakey in 1968. It explored the area as far as it could and found enough vertebrate fossils, including four hominid specimens, to encourage the National Geographic Society (staunch supporters of Drs Louis and Mary Leakey in Olduvai Gorge) to support a more extensive field programme the following year. Their faith was rewarded by further hominid finds, among them a complete cranium, and stone artefacts that appeared to be eroding out of one of the volcanic layers. Dating evidence indicated that the fossils were being collected from sediments laid down between 1 and 4 million years ago, with the younger localities tending to be in the north of the area and the older ones to the south.

Leakey had now moved to the National Museum in Nairobi. The museum authorities recognised the scientific importance of the work and since then the field expeditions have been organised from the museum, which has provided vital technical assistance and considerable logistic support. Despite the fact that many of the scientists involved are from Europe and the USA, the essentially Kenyan identity and basis of the expedition has never been in doubt.

For the 1970 season Leakey sought the assistance of Professor Glynn Isaac from the University of California. With Leakey leading the field team and the two acting jointly as scientific coordinators, they recruited geologists and palaeontologists and, with the continued backing of the National Geographic Society and a generous grant from the National Science Foundation (NSF), they began a planned programme of prospecting, excavations and earth sciences field work. Specialists were recruited to examine the fossils, both hominid and non-hominid, and by this time the scale of work necessitated the establishment of a permanent field camp at East Rudolf at Koobi Fora.

Like the creatures it set out to study, the expedition underwent its own evolution. As the involvement of the participating teams became deeper, and the importance of the laboratory and experimental support that was necessary for the field work was recognised, the East Rudolf Research Project was formed. This consolidated the close relationship of the research with the National Museum, and by means of a research council provided the museum with a panel of scientists which could advise not only on how best the current research could be prosecuted, but which

would also help to formulate future research policy for the area.

Research teams now come from both the USA and Europe to participate alongside the scientific staff of the National Museum. Each team is grant aided to a greater or lesser degree. The NSF in America and the Royal Society, the University of London and the National Environmental Research Council (NERC) in the UK have all provided support for research workers from many disciplines.

The maintenance of research teams many hundreds of difficult miles from the nearest town calls, however, for considerable basic logistic support in addition to that provided for by the research grants. Drinking water is several hours drive away from the main camp and a lorry is used solely to fetch water and firewood. Another lorry plies the barely passable tracks and roads to and from Nairobi with petrol and supplies. The buildings in the permanent camp have to be provided and maintained in an almost constant gale. To supply and maintain contact with small camps spread out over an area of thousands of square kilometres an aeroplane has been purchased which has since proved itself invaluable. To keep the twelve vehicles and two boats that are used in the field in good order a small garage has been built and for the field season a mechanic is resident at the main camp at Koobi Fora.

The responsibility for finding the funds for all these basic facilities has been accepted since the outset by Richard Leakey. Much of this money has been raised in the USA, a good deal of it from proceeds of lectures which serve the dual function of informing people of the research work

and raising the necessary funds. Paradoxically it is this willingness of a scientist to ask the public directly for money, instead of receiving it anonymously from the people through government and research grants, that seems, to earn the displeasure of some fellow scientists.

It is now a fact that the discovery of a possible ancestor of man several million years old is newsworthy. It is apparently also vexing that Richard Leakey, like his father before him, has a knack of exploiting this news to the advantage of his fund raising, and moreover doing it with a style and self assurance that is normally only associated with unravellers of double helices.

A more pertinent criticism of research programmes into human origins is that the very publicity surrounding the finds tends to concentrate judgement solely on results in terms of specimens recovered. There is an increasing tendency to judge sites according to their position in a hominid league table, with 'oldest' on one axis and 'greatest number' on the other. One would hope that, when scientific judgement is passed on these programmes, it will be on the basis of the quality of the scientific research and on the ability of the research workers to see beyond the immediate problems of the age and nature of the specimens. There is every sign that those bodies that support the research at East Rudolf appreciate the importance of the wider aspects of the research, while at the same time encouraging work on the fossils themselves.

Perhaps it is an encouraging sign of the maturity of hominid research that although research into the geological and palaeoenvironmental context of the material will be maintained at East Rudolf, and in some areas intensified, prospecting for hominid fossils has been temporarily suspended. This to give time for the sample of more than 120 hominids that have been collected to be assessed and analysed.

Only when the hominids are considered as just one faunal component, albeit an important one, of an evolving sedimentary basin, as is beginning to be the case at East Rudolf and at other East African sites, will hominid research this decade in Africa have shown itself to be a worthy descendant of Dart's pioneering efforts. That so much progress has been made, both in terms of available fossil material and in the manner in which its context is being studied, is to a large degree because of the scientific and organisational skills of two generations of the Leakey family.

A new centre for prehistory at Nairobi is to be called the Louis Leakey Memorial Institute. □

Fossil site, showing areas of exposed sediment

Transports of delight?

The two-car family on a half-acre plot, in an isolated suburb is no longer considered ideal in Canada, where there is new thinking on the inter-relationship between transport and a better life. Angela Croome reports.

INNOVATIVE transport is at the heart of urban planning. If anyone doubts this it is not Canada's metropolitan authorities. In particular the richest and fastest growing province, Ontario, has put its money (half a billion Canadian dollars since 1971, and an estimated \$1.3 billion over a ten-year period) on this approach to achieving better living. Furthermore, there is confidence that by pioneering a new type of urban transit system and the urban planning philosophy on which it is based, Canadian concerns will soon be supplying most cities of America (North, South and Central) and will acquire for Canada a major new industry and sphere of expertise.

Last year more cars than babies were produced in Canada. At the same time the country is 'urbanising' at a rate of 4% a year, so that if present trends continue, 73% of the population will be concentrated in 12 metropolitan areas by the end of the century. A combination of the need for economies in the use of space and energy and an increasing dissatisfaction with suburban commuter living based on the car has endorsed a radical change in urban planning policy. This was initiated by the Ontario government as far back as 1969 but was underscored in 1971 by a now historic decision to cancel an urban thruway (for motor traffic) in favour of investment in better public

transport. In 1973 the Ontario government succeeded in pegging public city transport fares while improving services by offering local authorities massive subsidies to promote re-equipment and replacement (75% of cost) and reimbursing 50% of the losses on public transport operations. This move has already been reflected in increased public transport 'ridership' figures in most communities.

The problem is seen as "planning better communities with built-in mobility and closer jobs for everyone". "The two-car family on a half-acre plot in an isolated suburb is seen less and less as the good life". Thus says the eloquent and busy F. W. Foley, President of the Urban Transportation Development Corporation based on Toronto. Mr Foley spends much of his time putting across the new thinking on the inter-relationship between transport and a better life in cities. Toronto, the provincial capital, is the focus of these experimental developments. This is appropriate enough, as it has the reputation of being one of the most attractive and best-run of large American cities—and it is at the centre of a region of almost frighteningly rapid growth. It could get itself into the kind of jam that has long since engulfed New York and may be sampled on a smaller scale on the London-Essex margin of the Thames.

Toronto is set to be the demonstration city where the new approach can be tested in practice and where people may come and see for themselves. (The need to keep public reaction in step at every stage is wisely not lost sight of.) Already it has introduced a dial-a-minibus service in outlying districts

Krauss-Maffei TUO-3: withdrawn

where the travelling public is too small to justify a fixed-route service or an underground rail connection. Staggered working hours have already been introduced in city centre offices with excellent results. For some time a city task force has been taking an overview of Toronto's urban planning and transport situation, and involving the public in decision-making. The large Exhibition Park on the city's lakeshore has been picked for the demonstration of the unconventional intermediate transit system labelled "GO-urban" that is at the centre of the planners' thinking. With a track circling the park it will provide links for visitors between the various exhibition halls while at the same time testing elevated track, in tunnel operations, driverless running, computer control, 'ride' comfort and the public reaction to all these elements.

The most significant step, however has been the recent establishment with a Toronto headquarters of the Ontario Urban Transportation Development Corporation (UTDC) with a national and international remit. It is a body without parallel in Canada, and perhaps anywhere else. It is a business institution created by special Act of the Ontario legislature enabling provincial investment to be made in research, design, development and production of public transport systems on a commercial basis. Its role combines that of a think-tank in the transport field with an investment and licensing business somewhat analogous to Britain's National Research and Development Corporation (NRDC). Its immediate object is, simply, to produce "new

transit technology". Provincial Ontario's investment in transport equipment in the next decade alone is forecast officially at over \$1,000 million Canadian dollars; it is already spending nearly \$10 million a year on technology and operational research in this field. The federal government in Ottawa is watching the Ontario initiative and its UTDC with close attention. The province of Alberta has already invested in the corporation.

The key element in the transformation of urban living that the Ontario authorities seek to achieve is the intermediate transit system, using unconventional design. Broadly the object is to obtain the speed and accessibility of an underground (subway) system, but in an overground context with the greater comfort associated with medium density travel—20,000 to 30,000 people in each direction each hour—without the environmental blemishes of noise, fumes and massive land use, and at a fraction of the cost per mile of tunnelling or motorway construction. A world-wide investigation of the state of the art in rapid transit development was completed in 1972 and eight systems were identified for follow-up.

The Krauss-Maffei "Transurban" and Hawker-Siddeley Canada concept (with collaboration from two British companies) were taken up as detailed projects and the Krauss-Maffei system was chosen in Spring 1973. A kilometre-long test track with curves and gradients was completed at the Krauss-Maffei facility at Munich while preliminary site work was started at the Exhibition Park in Toronto. The investment was worth \$30 million but with tough 'break' conditions.

In parallel with these moves by the province of Ontario, Ottawa's Federal Ministry of Industry, Trade and Commerce secured the seven-man linear motor design team from Cambridge, UK, when Tracked Hovercraft Ltd (one of the firms originally associated with Hawker-Siddeley Canada's project) was closed down by the British government. They went to work for the Toronto company SPAR, specialising in advanced technology and space vehicle systems, and the federal government has made a \$2 million industrial development grant to it for work on linear induction motors. SPAR was obviously going to be the major contender for the motor contract for GO-urban propulsion when things got that far. A test track for running a motor palette in various configurations up to 70 miles an hour is now ready at SPAR's Toronto site. This initiative well illustrates the fundamental approach of the Canadian authorities—a rate and massive effort to absorb and vitalise a new technology and a national asset.

A back door into the supposedly lush US market for unconventional rapid transit systems (its urban and automobile problems being similar) opened last autumn when the giant McDonnell Douglas aerospace company of California announced a licence from Krauss-Maffei to market the GO-Urban system in the USA and its territories, and a collaborative agreement with Ontario's UTDC to participate in the technology and development of the Toronto demonstrator.

Very recently the line-up of interests and participants has changed fairly radically with the announcement that Krauss-Maffei was pulling out of the Toronto GO-urban demonstrator project.

Under the cancellation terms Krauss-Maffei paid \$1,800 million immediate cash compensation to Ontario's UTDC, which in addition has the use of the Munich test track and a number of German technicians for two years, together with outright transfer of the accumulated technology, a royalty-free licence for Canada and a non-extensive licence for the rest of the world.

If anything the withdrawal of Krauss-Maffei has put the Canadians in an even stronger position astride the unconventional rapid transit business at least in North America. A question that British experts have been asking for many months is why did the assessors for the Toronto demonstrator plump for a maglev system. The pause may provide just the opportunity to

move to another combination of drive and suspension while reserving rights in maglev technology for other applications. At the speeds envisaged (up to 50 miles an hour) rubber-wheeled carriages propelled by linear induction motors would be equally quiet and non-polluting. They would also make less demands in electricity (for the levitating magnets have a separate supply). It is noteworthy that a combination of advanced linear motor propulsion with rubber wheel guidance and suspension is the type of palette that SPAR, focally placed in Toronto, is currently concentrating on.

The province of Ontario is spending far more on redesigning its public transport than is being spent nationally anywhere else. Its fundamental 'systems approach' must be admired, if not copied. It will provide a blueprint for other industrial countries with growing urban problems. Whether the pre-occupation with new technology to solve the intermediate capacity urban rapid transit problem will be justified remains to be seen; certainly there is no existing vehicle or system that fulfils the specifications set out. There appears little likelihood of lifting the urban scene out of the doldrums and freeing the citizen from the predominance of the car without dedicated central thinking and action, and here Ontario and Toronto in particular have done the world a service and growing cities everywhere would do well to study these developments. □

Eight developers of promising systems representing a range of new technologies were invited by the Ontario Transport Ministry to make technical submissions. The eight systems provide a good indication of world-wide trends in the use and application of new surface transport technology. Only a Japanese submission is lacking—the Japanese have concentrated their effort and investment on high-speed inter-city links.

System Name	Design concept	Automatic command/control	Suspension	Propulsion
Alden "StaRRcar" (USA)	PRT*	Yes	Rubber tyres	Rotary a.c. motors, hydrostatic drive
Ford "ACT"	Line-haul or PRT	Yes	Rubber tyres	Rotary d.c. motors
Transportation Technology inc. (USA)	PRT	Yes	Air cushion	Linear induction motors
Uniflo (USA)	PRT	Yes	Air cushion	Linear air turbine
Bertin "Aerotrain" (France)	Line-haul	Optional	Air cushion	Rotary or linear induction motors
Urba "30/100" (France)	Line-haul	Optional	Negative-pressure air cushion	Linear induction motors
Hawker-Siddeley Canada (Canada)	Line-haul with off-line stations	Optional	Rubber tyres	Linear induction motors
Krauss-Maffei "Transurban" (Germany)	Line-haul or PRT	Yes	Electromagnetic	Linear induction motors

* Personal rapid transit.

international news

AN unusually volatile mixture of politics and technology surfaced in the Commons in the first week of February. Its implications for the Canadian federal government's energy policy were serious enough, but because the case potentially pitted the strongly independence-prone Quebec government against an equally strongly federalist-minded Government of Canada, the outcome will be watched with great interest here.

In question was a deal Quebec officials had been quietly negotiating with representatives of France for construction in Quebec of a uranium enrichment plant to be known as CANADIF. This plant would cost from \$3,500 million to \$4,000 million. Because it would use the gaseous diffusion technique, it would require large amounts of electrical power (some 2,500 MW), and this power would be obtained from the James Bay development, an enormous hydroelectric project that itself has been a centre of controversy for some time. (Critics questioned how much of the James Bay power would be used for Canada and how much exported to the United States, and the Indians who lived in the wilderness that had to be flooded at first adamantly opposed the destruction of their hunting ground, then finally agreed after extended legal battles to accept payment of \$150 million and other concessions.)

In order to provide this power, extra capacity would have to be built into the James Bay station at a capital cost of \$1,500 million–\$2,000 million (roughly half the cost of the entire enrichment project). Even then, the enrichment plant would end up using a quarter of the hydroelectricity generated by James Bay—and the cheapest quarter at that. The uranium enrichment project would be used in part to exploit large uranium deposits owned by French companies in western Canada. But the enriched uranium would not be used in Canada, because Canada's own nuclear power system, CANDU, uses natural uranium fuel, unlike the French system. Furthermore, the export of enriched uranium would be used in the reactors of competitors to the CANDU system—perhaps not just the French, but the Americans as well.

All this at a time when Canada has restricted, and proposes eventually to eliminate, the export of energy in the

CANADIF raises energy policy problems

from David Spurgeon, Ottawa

Trudeau: no competition wanted

form of oil from Alberta and Saskatchewan to the United States—and at a time when Canada sees her own capital needs for energy as being approximately \$107,000 million in the next decade and when she has recently become so concerned about the use of her nuclear materials abroad that she has toughened up safeguard provisions at the risk of restricting her own CANDU sales.

The case came to light publicly when a number of documents showing the federal government's concern about the project were leaked to the Press, and Prime Minister Trudeau told the Commons that Canada is not interested in having enriched uranium exported in competition with the CANDU system. He said he had told France and Quebec about this disinclination, but he added that the federal government would still consider the deal if France, for example, wanted to build the plant itself, and if convincing arguments could be presented showing the scheme was in Canada's interests.

Commented *The Globe and Mail* of Toronto in its leader the next day: "It is difficult to see how the uranium enrichment plant proposed for Quebec would significantly enrich anybody except private industry, France and possibly some other foreign buyers."

One aspect that particularly worried critics of the scheme was that the consortium proposing it intended to amortise the cost over a period of only seven to eight years, and to give it a market lifetime of as little as 15 years, despite the fact that its technical lifetime could be 30 to 40 years. This seemed to indicate that they were hedging bets against the much cheaper centrifuge system of enrichment now being pursued by other European interests.

"Is Canada to be used as a colony, to provide supplies for the meantime, and then to be left with an antiquated plant on its hands?", asked *The Globe and Mail*.

The leaked documents showed how worried the federal government was that the Quebec government was trying to put the deal through quickly and quietly, thus presenting Ottawa with a *fait accompli*. This was not the first example of Quebec's attempts to establish a freedom of action usually associated with a sovereign state, and it was not the first example of France's desire to strengthen its influence and ties with francophile Quebec.

One of the leaked documents was a letter from the Federal Energy Minister Donald Macdonald, to Mr Trudeau. He described the consortium proposing the plant as consisting of Canadian Pacific Investments–Cominco (20%), Commissariat à l'Energie Atomique (40%), and the James Bay Development Corporation (40%). He said the consortium seemed to think the federal government's concern was solely with nuclear safeguards.

"The prospect that the federal government might withhold licensing of such a project because of economic considerations had never been contemplated." To show the importance of these considerations, Mr Macdonald attached a memorandum from his deputy minister, T. K. Shoyama, which noted:

- "(1) The federal government would have considerable concern over a large commitment towards an energy source to be utilised for the development of product destined entirely for the export market.
- (2) If there were a shortage of resources in the next decade, the government would want the available ones to be devoted to projects urgently required for the domestic economy.
- (3) For a project to be deemed in the

national interest it would have to be seen to be paying at least the average industrial power rate in the province, not the incremental cost of new power generated by Hydro Quebec, which is expected to be lower.

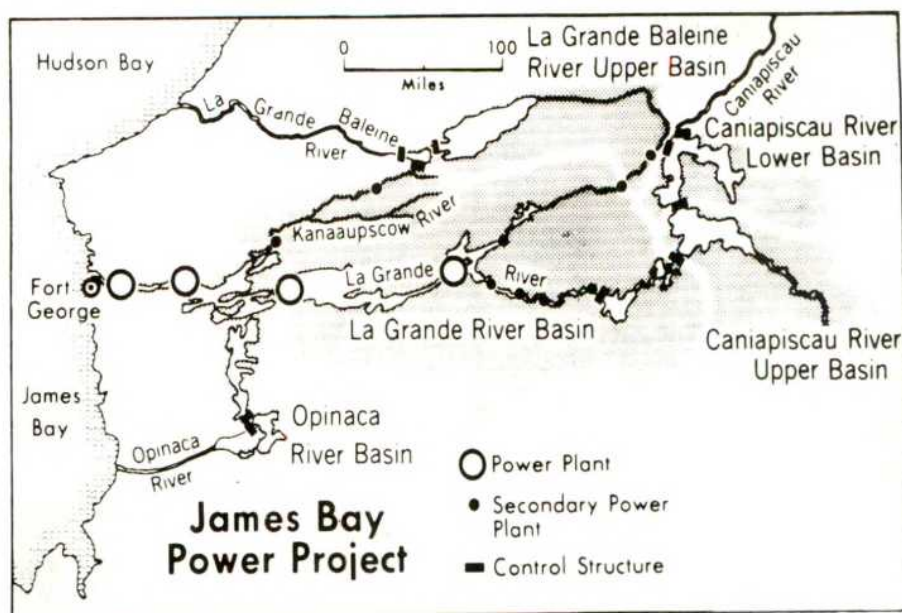

(4) CANADIF proponents wanted contracts for enriched uranium not to be interfered with for the life of the contracts, but 'Canada's safeguards policy could not be subservient to commercial considerations'. A country that might be an acceptable purchaser might later be found to be an unacceptable safeguards risk. If that proved to be the case, then the contract would have to be interfered with."

The memorandum made it clear that the federal officials feared Quebec's Premier Bourassa might try to enter into some commitment with the French government during a meeting he planned in December, and they warned Mr Trudeau and suggested he might speak to Mr Bourassa before that time.

Otherwise "it would be that much more awkward in the future for the federal government to refuse a construction permit through the licensing procedures of the Atomic Energy Control Board".

After his statement in the Commons, Mr Trudeau noted that even if non-Canadian uranium were used for enrichment and export by CANADIF, the federal government would remain concerned because large quantities of Canadian electricity would be required.

The irony of the situation is increased

when one recalls how proud Canadian atomic energy officials have always been in the past of the fact that the CANDU system itself does not need enriched uranium as fuel. For many years they had pointed out that the United States went along the enriched uranium route because she already had a massive investment in diffusion plants for nuclear weapons, while Canada, with no such plants, developed CANDU to exploit her abundant uranium deposits.

Until now, the Americans have been much more successful at selling their reactors abroad than have the Canad-

ians. Now there is the prospect of France exploiting Canadian uranium with the aid of Canadian electrical power in a period of power shortages, and selling it abroad not only to countries that may buy France's reactors but also to the United States.

By the end of the week, Premier Bourassa's only response had been that the CANDU reactor could be modified to use enriched uranium fuel. This is true, but it does not answer the question, why this should be done when CANDU was designed specifically so that it would not need enriched uranium. □

THE company formed to extract oil from the Athabasca tar sands in Alberta, Syncrude Canada Limited, has been saved by an injection of funds from the Canadian, Ontario and Alberta governments. The three announced they would invest \$600 million in the project in exchange for a direct share interest.

Until the announcement, the fate of the project—which aims to tap Canada's greatest potential source of hydrocarbon deposits—was in doubt. Last December, Atlantic Richfield Company of Los Angeles dropped its 30% interest because of mounting costs, currently estimated at \$2,000 million compared with the original estimate of \$195 million in the early 1960s. Shell Canada, which had shown an interest in joining Syncrude, later decided not to.

The remaining participants (Imperial Oil Limited, Gulf Oil Canada Limited, and Cities Service Company of Tulsa, Oklahoma) said they would abandon the project if they could not find additional partners.

So far, about \$160 million has been spent on the scheme. Syncrude scoops up the oil-saturated sand and then

separates the oil by means of hot water and steam. The site is near Fort McMurray, 225 miles north-east of Edmonton.

In return for its investment of \$300 million, the federal government will receive a 15% interest in Syncrude. Alberta gets a 10% interest for \$200 million, and Ontario 5% for \$100 million. Thus, governments will hold a 30% interest and private industry 70%.

Energy critics attacked the federal government's decision in the Commons after the announcement. T. C. Douglas, of the New Democratic Party, said "it represents the greatest sell-out of our natural resources in the history of Canada." He claimed it would benefit no one but the oil companies involved. And there is no way the government can avoid extending similar benefits to other companies, he said. Mr Douglas thought the government, together with other provincial governments that wanted to participate, should take over the project entirely.

Ontario's Premier William Davis sees it differently. He compared his province's investment to the gamble that was taken 100 years ago by those

who invested in the first railways across Canada. But Saskatchewan's Premier, Allan Blakeney, said that the federal government's decision to allow the Syncrude consortium to charge higher oil prices and greater tax deductions for royalties paid to the Alberta government is discriminatory, because his province's oil producers' prices are frozen and they cannot deduct royalties.

Subsequent questioning in the Commons made it apparent that the federal government's investment could climb higher than the \$300 million first promised. The Treasury Board President, Jean Chretien, said Ottawa's commitment is fixed at 15% of the costs, without an upper limit.

But it was not clear how high the investment would climb without question. Any major change in costs, Mr Chretien told reporters, would mean that "all the parties involved will have to sit down and review the situation."

It was also revealed later that Alberta's government will lend Gulf Oil and Canada Cities Service Limited \$100 million each, and will spend \$500 million—\$600 million on a power plant, pipeline and municipal services for the project.

Soviet biologist arrested in Moscow

from Vera Rich

THE arrest of the Moscow biologist Sergei Kovalev on December 27, 1974, seems to mark yet another hardening of Soviet pressure on dissident intellectuals.

Kovalev, whose main scientific work has been in the fields of mathematical biology and genetics (itself, until recently, a suspicious activity, by Soviet standards) is a member of Sakharov's Initiative Group for the Defence of Human Rights in the USSR, and also of a small group of Amnesty International, set up in Moscow in 1974. He has been active in the defence of prisoners of conscience within the USSR, and in campaigning for the free circulation of ideas and information. In 1974, when the *samizdat* "Chronicle of Current Events" resumed publication after an 18 month gap, Kovalev was one of the three dissidents who publicly claimed responsibility for its publication, being convinced "of the necessity for truthful information concerning the infringements of fundamental human rights in the USSR and for its availability to those interested." On the very day of his arrest, in a New Year's message telephoned to London, Kovalev and Sakharov appealed "from a huge and tragic country, the fate of which has huge influence on the life of the whole world" for a general amnesty for prisoners of conscience, mentioning among others mathematician Leonid Plyushch, biologist Vladimir Bukovskii, and psychiatrist Semeon Gluzman. "Let a general political amnesty open for our country and for all countries of the world the way to freedom and a good and sensible life."

The same day, Kovalev was arrested,

apparently on a charge of being in contact with the illegal *Chronicle of the Lithuanian Catholic Church*. This journal, which has a nationalist as well as a religious slant, has already been the cause of arrest of a number of Lithuanians; at the end of November, however, at the request of the Lithuanian KGB, a number of prominent Moscow dissidents, including physicist Andrei Tverdokhlebov, had their apartments searched. Like Kovalev himself, those involved do not appear to be Lithuanians, Kovalev's professional contacts with Lithuanians appear to be slight—only one of his published papers (*Biofizika*, 15, No. 1, 147–155) includes a Lithuanian, I. Dudzyavichyus, among the co-authors. He is, however, reported to have intervened in April 1974, in the case of a Lithuanian woman claiming US citizenship, who was arrested while attempting to reach the American Embassy in Moscow. It would seem difficult, simply on these grounds, to present Kovalev as a fanatic in the cause of Lithuanian separatism.

Nevertheless, the charge is that of possessing and disseminating copies of the *Chronicle of the Lithuanian Catholic Church*. Whether in fact Kovalev did, in his capacity as a campaigner for human rights, have some copies of this *Chronicle* in his possession is not known. The accusation does, however, have a number of advantages for the prosecution. Firstly, the case against the *Chronicle of the Lithuanian Catholic Church* has already been opened, and it is simply a matter of adding another name to the list of the accused, rather than opening a new case. Second, the trial will take place in Vil'nyus, capital of the Lithuanian SSR, away from the focus of attention which a Moscow trial would be for Western journalists. And thirdly, in a society

which extols atheism as "scientific", the attempt to implicate Kovalev with a religious journal may be, to a certain extent, a kind of smearing of his intellectual status.

Nevertheless, these moves to dispel publicity from the arrest and forthcoming trial have not met with unmitigated success. An appeal organised by Academician Sakharov on Kovalev's behalf has been signed by no less than 50 Soviet intellectuals, including linguists, mathematicians and research scientists. □

Toxic chemicals register first step

from Peter Collins, Geneva

BASIC agreement on the establishment and organisation of the proposed International Register of Potentially Toxic Chemicals (IRPTC), was reached at the meeting held at Bilthoven, Netherlands, last month (*Nature*, January 17). Interest in the meeting was considerably more than had been expected by its organisers, the Netherlands government and the United Nations Environment Programme, 57 scientists representing 27 countries and institutions being present. Besides the decision on basic organisation (a central unit correlating and disseminating data from a network of national sources) there was fruitful discussion of the type of work programme that could realistically be undertaken in compiling the register.

For this purpose, there should be an "intensive" programme, providing comprehensive information on a relatively small number of particularly important substances; and a much larger "extensive" programme listing a restricted number of attributes of many more compounds. The intensive programme, it is suggested, should start with a pilot project confined to a small number of chemicals; the object would be to test the best format for presentation of the material, to study means of collecting the data and checking their validity and to estimate the costs of operating this programme. The extensive programme, on the other hand, would be "open-ended", and might start by making use of information from existing data files. Use could be made of the facilities of the UNEP's International Referral System for Sources of Environmental Information (IRS) which is in a position to provide information on the whereabouts and capabilities of existing data collections. This initial survey should cover information of a fairly general nature as well as data on individual chemicals. It should be matched by a survey of potential users of the register, and could thus lead to a preliminary version of the proposed network directory which

"CHEMOSYNTHESIS", the reduction of metals from their ores by means of bacteria, is becoming an important field of research in the Soviet metallurgical industry, and is considered of great potential in the use of a wide range of ores from bauxite to gold agglomerates and uranium ores. Their use of bacteria ranges from the effective utilisation of ores such as the carbonate ores of manganese, where present methods lose up to 35% of the available metal (the chemosynthesis method yields up to 97.5% metal even from low-grade ores), to the extraction of gold and tin from arsenic-bearing agglomerates.

While some such processes are still only in the pilot-plant stage (the extraction of gold, manganese, bismuth, lead, antimony, lithium, or germanium) or

else exist only as theoretical projects (extraction of nickel, thallium, molybdenum, titanium and the microbiological lysis of aluminosilicates), some have already been introduced on a small industrial scale. Such plants, for the extraction of copper, uranium and zinc, are already operating in Kazakhstan and the Urals.

An intensive search is going on, in the research institutes of the Ministries concerned, to find new strains of thermophilic bacteria, multiplying at 55–60°C, which can reduce metal ores. The details of the processes involved remain obscure, but investigations on gold ores have given strong indications that the bacteria and other micro-organisms concerned are capable of forming organic compounds containing the gold in the course of their metabolic processes.

EXPENDITURE by the Department of Industry on research and development has risen 18% to £83 million in the year 1974/5 (*Report on Research and Development 1974*, HMSO £1.10). This barely keeps pace with inflation—even less so when allowance is made for £1 million or so of Rothschild-type transfers to the department in the last year. And when the applications and satellites (expenditure on which, in the form of subventions to the European Space Research Organisation, has risen in a year from £6.9 million to £15.4 million) are removed, the growth is decidedly negative.

Departmental expenditure on exploration and exploitation of the Earth has almost doubled in real terms in the last year to £5.5 million, all the new money going on the marine side. On the other hand civil aeronautics (excluding Concorde), hardly a booming business at present, declines 15% in real terms, getting £17 million of support.

Industry and government establishments now almost equally divide the department's money, industry having increased its share from 42% to 49%. The department's largest laboratories, however, the National Physical Laboratory and the National Engineering Laboratory suffer 10% cuts in real terms.

• Dr Walter Marshall, Chief Scientist at the Department of Energy, was given a rough ride last week by the Select Committee on Science and Technology who were clearly astonished at the lack of progress in formulating a strategy for Britain's research and development into means of energy conservation and developing new energy sources.

The Department of Energy is "still in a thinking period," Dr Marshall told the select committee when asked about the achievements of the multifarious committees that are currently worrying about energy. Dr Marshall and other members of the Advisory Council for Research and Development of Fuel and Power (ACORD) which reviews the research and development of the nationalised energy industries were closely questioned about the specific achievements of this body amongst others.

Dr Marshall said that he expected to produce a strategy in the next few months but that he did not like making promises. The matter of energy research was extremely complex and it had to be recognised that in energy research, the time scales between research and commercial application could be decades.

He was certainly disappointed that the level of spending on energy (other than nuclear power) remained at the present level, and the energy pro-

gramme will demand more money over the years. In the short term, Dr Marshall admitted that conservation schemes would be given priority over schemes to develop new sources of energy as they produced the most immediate savings. He defended the seeming lack of progress since his appointment six months ago by telling the committee that although it was necessary to get going on the energy programme quickly, it must be in the right direction, which meant a great deal of preparatory work.

Round Britain

• Before last year's somewhat abortive International Law of the Sea conference at Caracas, the responsible British minister at the Foreign and Commonwealth Office, David Ennals, held a day-long meeting in London which all interested parties could attend, ride their hobby horses and tilt at their favourite windmills. The Conference reconvenes in Geneva in March with a heightened need for agreements and a convention. On January 30, David Ennals chaired a second get-together at Church House but the level of argument seemed to have been pulled down by the overlong and over-strident proceedings at the international level at Caracas. A disproportionate time was spent on airing the narrow prejudices of the fishing industry presented as facts. The problem of enforcing penalties for oil pollution at sea seemed as far away as ever though a possibly practical suggestion was to invoke the responsibility of the port of origin as

well as the supposed flag of the offending vessel — too often one of convenience.

• The future of the Climatic Research Unit at the University of East Anglia now seems assured. After a period in which the work of the unit was severely hampered by uncertainty about where funds would be coming from over the next quinquennium, the Director, Professor Hubert Lamb, has been able to announce the award of several major grants to his team.

Largest of these is £100,000 from the Wolfson Foundation, covering the years up to June 1979 and "with no strings attached", says Professor Lamb. A Rockefeller Foundation grant of \$120,000 is specifically for a project on mapping and analysing available reports of weather, chiefly from various parts of Europe and Iceland, which cover many centuries in the past. This project will run until October 1977, and it is hoped to extend the analyses back for 1,000 years.

Professor Lamb has stressed the urgent desirability of increasing the number of staff in his unit, and a Nuffield Foundation grant of £24,228 will provide for the appointment of a Deputy Director from March 1976 to December 1979. The unit is also carrying out work under contract for various interested parties, including the City Authorities of Hamburg, who are interested in the incidence of disastrous storm floods in the North Sea, and the Commercial Union Assurance Company, which is supporting a three-year study of changes in the global incidence of tropical cyclones.

The dramatic turnaround in the unit's fortunes is also highlighted by Professor Lamb's future plans. His ambition for the unit to become more interdisciplinary in nature seems likely to be fulfilled, with a Nature Conservancy Council contract for a biologist to study effects attributable to climatic change on the distribution of the natural flora and fauna of the UK and North-west Europe, and "hopes of appointing an economist to keep watch on the impact of current climatic fluctuations on the world food situation, trade and other international aspects".

would be one of the main preoccupations of the central unit.

For positive identification of compounds included in any part of the register, use would be made of the Chemical Abstracts Service (CAS) Registry Number, which is already used by most data collections, although there will certainly be many instances in which this cannot be used.

A major problem may be the coverage of trivial and trade names of substances in languages other than English,

and it is here that international co-operation, especially with manufacturers, will be most necessary.

Consideration was also given to the hardware and software that will be required as the register is developed. One facility that could be of great use is the International Computing Centre, a UN inter-agency facility in Geneva, but it is appreciated that not all storage of data will be computerised, especially in view of the marked interest in the register already being shown in some of the

developing countries.

The presence of scientists from the Soviet Union and Hungary, as well as from Brazil, Ghana, Togo, the Philippines, Tanzania and India, in addition to almost all the highly industrialised countries, shows that the need for this new move in environmental protection is widely appreciated.

With a bit of luck the work of the group will not be hamstrung by the economies being applied elsewhere in the United Nations system. □

A COMMITTEE of the National Academy of Sciences last week shook the foundations of energy planning in the United States by suggesting that domestic supplies of oil and gas may dry up in 25 to 30 years, much sooner than the government has been forecasting. If the committee's estimates turn out to be correct, deep trouble is in store for the much-vaunted drive to make the United States less dependent on imported oil to meet its energy needs.

The estimates form part of a 2-year review of minerals supply and demand, conducted by the academy's Committee on Minerals Resources and the Environment (COMRATE). The committee's central, and inescapable, conclusion is that much more vigorous conservation efforts are needed, not only for oil and gas, but for various other materials as well. As COMRATE's chairman, Dr Brian J. Skinner, professor of geology and geophysics at Yale University, put it last week, conservation should become "almost a religion" if serious dislocations are to be avoided.

Although there is no single "official" estimate of oil and gas resources in the United States, those most commonly used for government planning have been developed by scientists working for the US Geological Survey (USGS). The USGS figures generally suggest that domestic production of oil and gas can be expanded over the next decade, and that supplies will be good for at least 40 or 50 years.

But those forecasts have been challenged recently by much of the oil industry and a number of distinguished experts. They have argued that the USGS's estimates are grossly overblown and that domestic resources are already beginning to dry up. COMRATE's entry into the fray last week with an estimate that broadly supports USGS's critics is likely to sharpen the debate considerably.

The importance of the dispute is this. If the USGS's figures are correct, expansion of oil and gas production in the United States over the next decade or so will be a great help in alleviating dependence on Arab oil. Projections developed last year by the Federal Energy Administration, for example, envisaged domestic oil and gas production going up by more than 50% by 1985, given the economic incentive of high oil prices and some governmental support. But if the USGS's critics are correct, expanded domestic production can be virtually ruled out. Moreover, there will be an acute need to develop alternative fuels (such as synthetic petroleum and gas from coal, and oil from shale) as quickly as possible.

There is virtually no dispute about the size of the so-called "proven" reserves—those which the oil industry

Bad news for US energy planners

by Colin Norman, Washington

has already found and believes it can exploit commercially with conventional technology. The nub of the disagreement concerns the extent of oil and gas deposits which have yet to be discovered—the so-called undiscovered recoverable resources.

In March last year, USGS Director Vincent McKelvey published a set of figures suggesting that undiscovered oil resources in the United States and offshore amount to between 200 and 400 billion barrels, while undiscovered natural gas resources total between 990 and 2,000 trillion cubic feet. By comparison, estimates developed by two oil companies last year put the oil reserves at about 90 billion barrels and gas reserves at about 400 trillion cubic feet. Now COMRATE has come up with a forecast that about 113 billion barrels of oil and 530 trillion cubic feet of gas remain to be discovered.

Surprisingly, those estimates differ little on the extent of oil and gas resources in Alaska and offshore, although COMRATE estimates that fully 70% of future supplies will come from those areas. The chief discrepancy is to be found in the forecasts for the extent of undiscovered deposits onshore in the lower 48 states, and that fact is surprising because the continental United States is about the most extensively drilled area in the world.

The difference is explained by the fact that there are two schools of thought about how the resources should be measured. The oil industry says that the USGS estimates fail to take sufficiently into account the trend of declining oil production per foot of drilling over the past few years, while the USGS says that the oil industry's estimates pay insufficient attention to potential production from small fields.

Until recently, USGS's figures were based essentially on a method which involves extrapolating production rates for oil and gas from known fields to similar geological deposits elsewhere. But that methodology has come under increasing attack, most prominently by M. King Hubbert, a geologist who used to work for Shell, but who now works for the USGS. Hubbert maintained, as long ago as the 1950s, that such predictions are based on production data from the richest parts of existing fields, and thus fail to take into account the fact that the amount of oil produced per well in a given field declines with the number of wells drilled. In other words, the oil com-

panies have creamed off the most productive areas of Texas, Oklahoma and California and information from those areas is unreliable as a guide to what is likely to be found elsewhere.

The USGS's more recent estimates have gone some way towards meeting Hubbert's objections, since they assume that unexplored areas will be only about half as productive as areas which have already been exploited. But Hubbert argues that even those revised estimates will prove to be much too optimistic. A better estimate, he says, is that they will be about one tenth as productive.

Hubbert has at least one important piece of evidence in his favour. In the mid 1950s, he predicted that domestic oil production in the United States would peak in the late 1960s and thereafter would decline; the USGS was then estimating that the peak would not come until the mid-1980s at least.

As it turned out, the peak came in 1970. Hubbert's critics point out that environmental constraints, coupled with a moratorium on offshore oil drilling, may have been responsible for some of the decline since 1970, but Hubbert's arguments have steadily gained acceptance in the oil industry, and in particular they have forcefully been taken up by John Moody, a former official of Mobil Oil and now a consultant to the oil industry. Moody, who was a member of the COMRATE panel, estimated last year that undiscovered oil reserves amount to about 90 billion barrels.

For its part, COMRATE has come close to accepting the validity of Hubbert's approach. Its report states that the projections developed last year by McKelvey "could have been more rigorously derived" and COMRATE's estimate that undiscovered reserve amount to about 113 billion barrels is closer to Hubbert's prediction than to that of the USGS.

Asked what effect he expects the COMRATE report to have, Skinner said last week that "now that the National Research Council (the operating arm of the National Academy of Sciences) has put out a report that comes down in favour of the lower figures, not firmly but at least in favour of them, there will be a lot of pressure on the Geological Survey to justify its methods".

A USGS official noted, however, that oil resources have consistently been underestimated by the oil industry in the past. "Who is to say who is right?" he said, "We are not going to back off from those figures just because they are high". The USGS is, however, updating its estimates and hopes to have a new set of figures, based on the most recently available geophysical data ready by April.

Io, the anomaly of the Solar System

from a Correspondent

JUPITER is surrounded by an extensive system of 13 satellites. They include four large planetary bodies Io, Europa, Ganymede and Callisto whose sizes are similar to that of our Moon. These satellites reside in the region of trapped radiation around Jupiter and their interaction with the Jovian environment is much greater than the Moon's with the Earth's magnetotail. But it is Io that is the anomaly, not only among the Galilean Satellites but also among all the bodies of the Solar System.

The density of Io, 3.5 g cm^{-3} , is the highest of the Galilean Satellites and comparable to that of the Moon and Mars. In general high-density bodies ($\rho > 3$) are probably rocky silicate structures whereas low density objects ($\rho < 2$) may have a large percentage of ice. During the Pioneer 10/11 flybys, it was found that Io efficiently absorbed electrons in the range 0.16–9 MeV (Fillius and McIlwain, *J. geophys. Res.*, **79**, 3589; 1974; and Simpson *et al.* *J. geophys. Res.*, **79**, 3522; 1974) but had little effect upon electrons of higher energies. Earth-based radio observations had shown that the position of the satellite on its orbit influences the

decametric radio bursts from Jupiter.

Visual astronomers discovered a further puzzling feature. Some reported an increase in brightness of 0.1 mag lasting as long as 15 minutes upon re-emergence of the satellite from Jupiter's shadow though other observers have failed to detect any change in brightness. Does this suggest that the satellite may have an atmosphere? Certainly one would not expect a planetary body with such a low surface gravity to possess a substantial one, so that the discussions of an atmosphere on Io have always been controversial.

But Io does have an atmosphere and an ionosphere too—it is the smallest body in the Solar System with such features. The ionosphere was detected during the Pioneer 10 flyby (Kliore *et al.*, *Science*, **183**, 323; 1974) and was found to extend to some 700 km above the surface with a peak electron density of about $6 \times 10^4 \text{ electrons cm}^{-3}$ at an altitude of between 60 and 140 km on the dayside. A thinner and less dense region was observed on the nightside with a peak density of $9 \times 10^3 \text{ electrons cm}^{-3}$ at an altitude of 50 km.

The diminished nightside ionosphere indicates that this region is produced by the action of solar radiation on the dayside and then decays during the 21 hour Io night.

The Io atmosphere is tenuous, with exotic constituents sodium, calcium, hydrogen, possibly also ammonia and nitrogen, and a surface pressure of between 10^{-8} and 10^{-10} bar. Sodium emission from the satellite's atmosphere provided Brown and Chaffee (*Astrophys. J.*, **187**, L125; 1974) with the first positive evidence for the atmosphere. Trafton, Parkinson and Macy (*Astrophys. J.*, **190**, L85; 1974) reported that the emission came from an extended space around Io. The total column abundance of sodium is estimated to be roughly 10^{11} cm^{-2} in this extended cloud and 10^{13} cm^{-2} in the atmosphere of Io.

As well as the sodium cloud, there is around Jupiter in the orbital plane of Io an extensive cloud of atomic hydrogen (Carlson and Judge, *J. geophys. Res.*, **79**, 3623; 1974). The mean diameter of the torus is about equal to the diameter of the orbit of Io. The torus is not complete, however, but seems to

JOVIAN thunderbolts, occurring at a rate of one per square kilometre of Jupiter's surface every 10 min, may explain the presence of acetylene in the clouds of the giant planet.

Both ammonia and acetylene have been detected in Jupiter's atmosphere, and since both would be rapidly photodecomposed they must be being continuously produced by processes operating in the planet's atmosphere. According to Bar-Nun (*Icarus*, **24**, 86; 1975) ammonia could be produced in the hotter deep layers of the atmosphere and persist for long enough to be carried upwards by convection into the layers where it is detected. But the lifetime of acetylene under Jovian conditions is so short that it must be made closer to the top of the atmosphere.

Bar-Nun's model, which is backed up by laboratory experiments, suggests that the shock waves of thunderstorms are the chief mechanism by which acetylene is produced on

Great Red Spot plastic wrapped by Jovian bolts

by John Gribbin

Jupiter. The electric discharges of lightning will themselves contribute to some extent, but a much greater volume of gas is affected by the thunder,

with the result that significant quantities of methane are converted to acetylene. Ammonia will also be produced in this way, together with hydrogen cyanide, cyanogen and other compounds.

Taking a typical terrestrial storm as a guide, Bar-Nun calculates that $5.3 \times 10^4 \text{ km}^{-2} \text{ yr}^{-1}$ thunderbolts would be needed to produce the amount of acetylene detected. Since Jovian bolts are likely to be more impressive than their terrestrial counterparts, the number may in fact be rather smaller. The compounds produced in these shock waves are almost ideal for explaining the puzzle of Jupiter's colouration, with yellow-brown acetylene polymers and ruby red polymers containing hydrogen cyanide and cyanogen predominating; the correct colour intensity for the Great Red Spot could be produced if thunderstorm activity in the spot is larger than the Jovian average by an order of magnitude.

extend for 60° on either side of the satellite. The lack of emission from that portion of the cloud which happened to lie in Jupiter's shadow suggests that the cloud's diameter is smaller than that of Jupiter and that resonance scattering of sunlight is the primary excitation mechanism.

A torus of this type is thought to be formed by atoms which can escape from the satellite but do not possess sufficient energy to escape from the vicinity of the planet owing to its large gravitational field (McDonough and Brice, *Icarus*, **20**, 136; 1973). Consequently the atoms are bound in closed orbits until lost by ionisation or recapture and tend to produce a toroidal shaped cloud whose density is determined by the ionisation losses. The cloud around Jupiter has a brightness of about 10^4 Rayleighs, composed of roughly 10^{23} hydrogen atoms with a mean lifetime of $\sim 10^5$ seconds. This is slightly longer than Io's orbital period.

But is Io the source of the toroidal hydrogen? The escape of hydrogen from Io poses no problem, since the Jeans escape from an exosphere as cold as 200 K is still very efficient. In order to maintain the cloud the satellite must be supplying hydrogen at a rate of 10^{11} atoms $\text{cm}^{-2} \text{s}^{-1}$. An escape flux of this magnitude would exhaust the entire atmosphere of Io in a few years. Is the surface of Io abundant in hydrogen-rich material?

There are several other puzzling questions regarding the surface of Io, a principal one being of course why it has such strong sodium emissions. Also, why is Io as bright as if it were covered by ice, yet shows no ice absorption features in its spectrum? And why has Io dark poles?

Fanale *et al.* (*Science*, **186**, 922; 1974) suggest that Io's surface composition involves evaporite salt deposits which are rich in sodium and sulphur. (This would both provide a source of sodium and explain the brightness of the planet.) They believe that unlike the other Jovian satellites, Io never had large amounts of ice, yet it apparently was not totally devoid of water like our Moon. As a result of internal degassing, much of Io's water may have seeped to the surface, where it would quickly evaporate as a result of the satellite's proximity to Jupiter and its low surface gravity. The high density of Io and absence of H_2O ice bands in the surface spectrum may mean that this process is essentially completed. Fanale *et al.* speculate that the internal processes are considerably less advanced on Europa and Ganymede, satellites which are apparently very different from Io.

Salt-rich assemblages that Fanale *et al.* propose for the surface of Io are easily derivable from the leaching of carbonaceous chondritic material.

Matson *et al.* (*Astrophys. J.*, **192**, L43; 1974) suggest that the sodium observed in the atmosphere is sputtered from Io's surface by the charged particle bombardment and these atoms could populate the cloud observed beyond the satellite. This mechanism may also be responsible for the calcium emission which Meckler and Eviator (*Astrophys. J.*, **193**, L151; 1974) have observed at 4,427 Å. The previously unexplained colouration of the surface must therefore result from the Jovian magnetospheric fluxes being strongest at the poles of Io.

The presence of ammonia on the surface and in the atmosphere of Io is still controversial, but is required by McElroy *et al.* (*Astrophys. J.*, **187**, L127; 1974) to explain the strong sodium emission. Their hypothesis of the mechanism of sodium emission predicted the ionosphere we have now observed. They suggest that if Io's atmosphere contains $\sim 10^{18}$ molecules cm^{-2} of ammonia, its photolysis would lead to the production and escape of hydrogen at the rate of 2×10^{11} atoms $\text{cm}^{-2} \text{s}^{-1}$. This process represents a net absorption of solar energy and heats the upper atmosphere to around 500 K. Nitrogen would be an important minor product, which when excited by an auroral mechanism could interact with sodium to cause sodium emission. McElroy *et al.* suggest that sodium photoionised by solar radiation may be the dominant source of ionisation. The aurorae possibly resulting in the

sodium emission may draw energy from the current arches to Jupiter, so that significant localised atmospheric heating may result, providing for thermal escape of exospheric sodium into the surrounding cloud.

The Io-controlled radio activity of Jupiter is highly sporadic so that a synoptic patrol of the brightness of the sodium emission may be used to examine the various roles suggested for the high energy particles. But Bergstrahl *et al.* (*Astrophys. J. Lett.*, in the press) found that the resonant scattering of sunlight was primarily responsible for the brightness of the sodium cloud. Auroral processes may still be important for the near surface emission and for heating sodium to its high kinetic temperature. The stability of the cloud over 43 nights of observation implies a remarkably steady source of sodium, since the mean lifetime of steady sodium is less than 16 days.

Io is an anomalous fragment of primordial material bathed in a violent electrical environment which modifies and erodes it. The Jupiter-Io system represents a unique environment where two atmospheres are mutually interacting on a large scale through a magnetic field (for example Goldreich and Lynden-Bell, *Astrophys. J.*, **156**, 56; 1969). Correlated ground-based observations, as well as *in situ* measurements from spacecraft are still required if we are to fully understand this strange planetary body and its interaction with the Jovian environment.

Cosmic rays from the Galaxy

from a Correspondent

THE origin of the high-energy cosmic ray particles ($\geq 10^{17}$ eV) remains a mystery. The long existing controversy on whether the particles observed at the Earth originate inside or outside the Galaxy seems however to be nearing resolution; evidence is accumulating in favour of Galactic sources.

The primary particles are difficult to detect because of their low flux $\sim 1 \text{ km}^{-2} \text{ yr}^{-1}$ at 10^{19} eV. Use is made of the atmosphere as a detecting medium by observing the extensive air showers (EAS) initiated by the primary particles. The secondary particles produced in one of these showers spread out laterally and can be picked up by an array of detectors over an area of several kilometres at sea level. The direction of motion of the original incoming particle can be estimated (typically with an accuracy of about 2°) by timing the sweep of the front of the

EAS across the detector array. By building up statistics over periods of years the distribution in arrival direction of the primaries can be determined.

There are several large EAS detector arrays situated around the world, most notably at Haverah Park, near Harrogate (England), Volcano Ranch (New Mexico), Yakutsk (USSR) and Narrabri near Sydney (Australia). Until very recently the combined results of all the arrays have failed to show up any evidence that was inconsistent with the complete isotropy of the arrival directions of these high energy particles. At lowish energies this is not too surprising as the magnetic fields in the Galaxy can churn up the particles so that on detection their direction of travel bears no resemblance to the direction of their original source.

Sufficient data on the EAS above 10^{17}

eV have now been accumulated, however, and these clearly indicate, for the first time, that there is some degree of anisotropy in arrival directions. By combining together data from the four arrays Krasilnikov *et al.* (*J. Phys.*, **A7**, L176; 1974) have analysed 76 events above 10^{19} eV arriving at the Earth from the northern celestial hemisphere. In an harmonic analysis in right ascension of the arrival directions of these particles a first harmonic amplitude of roughly 40% appears with a maximum occurring about 13 h RA. The authors calculate a chance probability of only $\sim 2.6\%$ for such an effect and add supporting evidence for it being real from data accumulated on lower energy EAS.

Such an anisotropy has obvious importance in connection with the origin of the particles. Hillas and Ouldrige (this issue of *Nature*, page 609) point out that this adds weight to the Galactic origin theories, supporting arguments based on other experimental data including the absence of a cut-off in the energy spectrum below 10^{20} eV due to 2.7 K photons. Plotting the available data on full celestial coordinates Hillas shows that the anisotropy in RA arises from a definite clustering of the arrival directions in at least three regions of the sky. Such separate clustering does not suggest a single distant source but rather a Galactic origin. With this in mind Hillas and Ouldrige further suggest, to explain the total cosmic ray energy spectrum, that the mode of propagation existing below 4×10^{15} eV, consistent with cosmic rays escaping along magnetic field lines, is overtaken at higher energies continuing right up to 10^{20} eV, by a more rapid drift, perhaps radially outwards across the field lines. This suggestion leads to an explanation of the position of the most prominent of the observed clusters. But as the authors point out, to retain nuclei at about 10^{20} eV (the highest energies so far observed) would require a magnetic field extending several kpc from the Galactic plane and even then with a field magnitude of about 2×10^{-6} gauss only relatively heavy nuclei could be contained. There is some other evidence from observations at radio frequencies of the presence of such an extended magnetic field.

Unfortunately it will take several more years of EAS observation to add significantly to the statistics of the anisotropy. Meanwhile at Haverah Park and elsewhere attention is strongly directed towards determining the mass of the primary particles in the energy range $\sim 10^{19}$ eV. Evidence in favour of a high proportion of multi-nucleon primaries at these energies would give good support to the Galactic theories.

Redshifts of BL Lac objects

from R. F. Carswell

BL LAC is the prototype for a class of astronomical objects which has been the subject of a good deal of observational and theoretical work over the past two or three years. Generally, objects of this type are notable for their rapid variations in intensity and polarisation at all wavelengths where these quantities can be observed, and for the absence of any discrete features in their spectra. Some, notably BL Lac itself and, for example, AP Lib and Markarian 501 seem to be surrounded by nebosity and so look rather like galaxies with exceptionally bright nuclei, similar to Seyfert galaxies. Others, such as OJ287, are stellar in appearance and could be related to the quasi-stellar objects, though without any of the emission lines from which a redshift can be determined. In the case of such star-like continuous objects we can only conjecture at their distance from us, since no angular size or redshift can be measured, but for objects with nebosity we can hope to obtain estimates of their distance by looking for observable features in the galaxy component.

Just such an observation has been performed in the case of AP Lib by Disney, Peterson and Rodgers (*Astrophysical Journal Letters*, **194**, L79; 1974) using a number of spectra taken at the Mount Stromlo Observatory in Australia. They noticed that a number of features could be seen very weakly but consistently on their plate material gathered over a period of time, and found that these correspond to lines often seen in normal galaxies if AP Lib has a redshift of $Z=0.0486$. With the currently accepted value of $50 \text{ km s}^{-1} \text{ Mpc}^{-1}$ for the Hubble constant, this corresponds to a distance of about 300 megaparsecs, and the angular size of the galaxy is roughly what we might expect at that distance.

An earlier attempt to find a redshift for a BL Lac object by looking for galaxy features in an extended halo had been described by Oke and Gunn (*Astrophys. J. Lett.*, **189**, L5; 1974). They used a rather different technique, employing a diaphragm to block out the light from the central object so that the galaxy lines would stand out more clearly, and their observations was of the prototype object itself, BL Lac. The absorption features they found were also very weak, but could correspond to a redshift of about 0.07.

There is however considerable doubt about the redshift in this case. More recent observations by Baldwin, Bur-

idge, Robinson and Wampler (*Astrophys. J. Lett.*, **195**, L55; 1975) show no absorption features, and so no evidence that the nebosity around BL Lac is made up of a normal galaxy of stars. They suggest that perhaps one reason for the difference in the results obtained is that a nearby very faint star may have contaminated the spectrum from which Oke and Gunn determined their value. Though the true nature of BL Lac must await further observational work this disagreement between two groups does highlight some of the difficulties involved.

Another BL Lac object, PKS 0735+178, is believed to have an even higher redshift and to be more QSO-like in character. A group of astronomers working in Arizona reported in June last year (Carswell, Strittmatter, Williams, Kinman and Serkowski, *Astrophys. J. Lett.*, **190**, L101; 1974) that a strong pair of absorption lines corresponding to MgII with a redshift of 0.424 had been found in this object. A number of QSOs show sharp absorption lines in their spectrum, always at redshifts lower than, or comparable to, the emission line redshift, and it is believed that in PKS 0735+178 we are seeing the same type of thing. This does not tell us the redshift of the continuum source, however, but it is extremely unlikely that it is much less than 0.424, and probable that it is at about that value.

Apart from placing BL Lac objects clearly well outside our own Galaxy, these redshift determinations can help to test our understanding of the physics

A hundred years ago

THE *Kölnische Zeitung* of Feb. 10 gives an account of Prof. Böhm's (Dorpat) researches on revival after cases of poisoning. He succeeded in reviving cats which had been poisoned by injection of potash salts into their veins, after forty minutes' duration of a state which was in no way different from actual death, the action of the heart and respiration having completely ceased. He obtained these results by artificial respiration and simultaneous compression of the breast in the vicinity of the heart. The professor points out the importance of the latter point, which he deems as essential as the action of the lungs. In any case his researches are of high interest for the relation they bear upon the revival of poisoned persons.

from *Nature*, **11**, 334; February 25, 1875

of such sources. The light and radio emission varies in intensity extremely rapidly; so rapidly that in some cases quite large changes can occur in times of only a day or two. It is very difficult to see how, without signals propagating with speeds greater than light, something can vary on time scales shorter than the light travel time across it, and so this means that the BL Lac objects emit most of their radiation from a region less than a light day or two across. Now if these objects are a very long way away, for example at what might be called 'near quasar' distances, it becomes extremely difficult to understand how the large amounts of radiation required to give the observed brightnesses can be released in so small a volume. Now that we are in a position to say that the redshifts in some cases are quite large, we have the situation where, as Jones (*Astrophys. J. Lett.*, **191**, L15; 1974) and others have pointed out, it seems likely that our understanding of the radiation processes is inadequate, or that perhaps these objects are really closer to us than their redshifts indicate.

Textured superfluids

from P. V. E. McClintock

In a recent communication from the Low Temperature Laboratory of the Helsinki University of Technology, Ahonen, Haikala, Krusius and Lounasmaa describe their transverse nuclear magnetic resonance experiments on superfluid ^3He over a wide range of pressures and temperatures down to 0.7 mK (*Phys. Rev. Lett.*, **33**, 1595; 1974). Their data seem to be consistent with the suggestion by Brinkman, Smith, Osheroff and Blount (*Phys. Rev. Lett.*, **33**, 624; 1974) that the B phase of the superfluid is anisotropic and may be expected to exhibit textures somewhat analogous to those of liquid crystals.

More than 80 papers, mostly theoretical in nature, have been written on superfluid ^3He since the original experiment in 1972 at Cornell University by Osheroff, Gully, Richardson and Lee (*Phys. Rev. Lett.*, **29**, 920; 1972) which led to its discovery. This continuing flurry of activity arises from the entirely novel states of matter which are involved.

It is now known that, below a transition temperature T_c , there are two distinct superfluid phases, referred to as A and B. The phase diagram has been mapped out by various workers and is apparently as shown in Fig. 1. Although, as can be seen, the A phase is stable only within a relatively small area of the P - T diagram, much more is now known about it than about the

lower temperature B phase. The reasons are mainly cryogenic in origin. The two previously existing methods of cooling liquid ^3He —compressional cooling along the solidification line, and adiabatic demagnetisation of the electronic spins of

Fig. 1 The phase diagram of liquid ^3He in small magnetic fields at very low temperatures (after Paulson, Kojima, and Wheatley, *Phys. Rev. Lett.*, **32**, 1098; 1974; and Ahonen *et al.*, *Phys. Rev. Lett.*, **33**, 628; 1974). The dashed line indicates the lowest temperature to which the liquid has yet been cooled. Note that the vapour pressure at these temperatures is so small that the liquid-vapour equilibrium line comes within the thickness of the abscissa as drawn here.

cerium magnesium nitrate (CMN)—allow the whole of the A phase to be investigated, but are capable of achieving temperatures only just within the B phase. The technique of nuclear demagnetisation has been applied successfully to cooling liquid ^3He only recently, when the same group at Helsinki reported (*Phys. Rev. Lett.*, **33**, 628; 1974) that they had managed to reach 0.7 mK using this method, thus opening up the temperature range required for a detailed investigation of the B phase of the superfluid.

Why and how does ^3He become superfluid at these low temperatures? It is now almost universally believed, in spite of one or two nagging discrepancies between theory and experiment, that both A and B phases have much in common with the electron gas in a superconducting metal. In each case, the total energy of the particles, whether electrons or ^3He atoms, is reduced if they form so-called Cooper pairs. There is however an important difference in that, for superfluid ^3He , pairs are formed whose relative angular momentum is non-zero, whereas the Cooper pairs of all known superconductors have zero angular momentum. Thus, a Cooper pair in ^3He consists of two atoms orbiting around each other. Much of the experimental and theoretical effort has so far been devoted to investigating how this orbital angular momentum is correlated with the directions of the nuclear spins of the two atoms, and most of the information has been derived from experimental investi-

gations of nuclear magnetic resonance (NMR).

When a single ^3He atom is placed in a magnetic field its nucleus, which has a magnetic dipole moment of its own precesses about the field direction in one of two permitted states, corresponding to two different energy levels. In NMR the resonant absorption of electromagnetic energy at the so-called Larmor precession frequency enables the splitting of the energy levels to be measured. When Cooper pairs are formed, however, the nuclei are no longer acting independently of each other. A careful investigation of the NMR resonant frequency, linewidth and integrated intensity, all of which are found to change from their value in normal, that is non-superfluid, ^3He , therefore yields information about the way in which the nuclear spins and orbital angular momenta are correlated with each other and with possible axes of anisotropy in the liquid.

It seems to have become well accepted that the A phase is in the particular state originally proposed by Anderson and Morel (*Phys. Rev.*, **123**, 1911; 1961) with the nuclear spins of each Cooper pair lined up parallel to each other in the plane of their mutual orbit which has an angular momentum of magnitude $1\hbar$, and with the orbital momenta of all the pairs aligned and perpendicular to an externally applied magnetic field. This implies, of course, that the liquid itself will be anisotropic; that is, many of its properties will depend on the direction relative to the axis of anisotropy in which measurements are made. The Helsinki group's transverse NMR measurements are the first to be made at pressures other than on the solidification line, and it is reassuring to note that their results are in good agreement with predictions based on the assumption of the Anderson-Morel state. In particular, it seems that the pressure dependence of the shift in resonant frequency from its value in normal ^3He is well accounted for by the relation which had been derived theoretically by Leggett (*Phys. Rev. Lett.*, **29**, 1227; 1972) on the basis of that assumption.

It is the lower temperature results of the Helsinki NMR experiments, those in the relatively unknown B phase, therefore, which are in many ways the more interesting. The B phase has been tentatively identified as the state originally proposed by Ballian and Werthamer (*Phys. Rev.*, **131**, 1553; 1963), in which the pair orbital angular momentum is again $1\hbar$, but for which the correlation of orbit and nuclear spins is considerably more complicated than in the Anderson-Morel state. Brinkman *et al.* have been able to demonstrate, however, that it should be possible to define a single axis of

Registry of abnormal karyotypes

AN international registry of abnormal chromosomes has been set up by the Division of Medical Genetics of Johns Hopkins University. Dr D S Borgaonkar and Mr D R Rolling have been gathering data into a computer for the past eleven months and hope to continue to receive details of new and existing human chromosome abnormalities. They aim to establish a sufficiently comprehensive collection to provide information about the prevalence of human conditions, such as Down's syndrome, which are characterised by chromosome abnormality, and to give cytogeneticists a means of exchanging data which might otherwise be lost in their files.

The computer records the name of the person reporting the karyotype, the laboratory where the work was done, the date it was reported, and the arm, region and band of the chromosome on which the rearrangement responsible for the abnormality was found. The registry is being organised on a basis similar to that of Dr Borgaonkar's book *Chromosomal Variation in Man: A Catalog of Chromosomal Variants and Anomalies* (Johns Hopkins University Press, Baltimore, in the press). The book, which was compiled with help from the Institute of Medical Research at

Camden, New Jersey, where there is a repository of abnormal karyotype cultures, and Dr F Ruddle's laboratory at Yale University, consists chiefly of published information. The registry, on the other hand, is being compiled mostly from unpublished data. Print-outs are planned to appear two or three times a year and will be available at cost.

Dr Borgaonkar hopes that, using data in a similar way, it will be possible to catalogue break-points on the mammalian X chromosome of different species to reveal 'hot spots', where unusually large numbers of breaks are reported. He also foresees catalogues of chromosome variation for species such as the common mouse, *Mus musculus*, which has well defined chromosome regions.

The response to requests for data so far has been encouraging. Some regional centres have been set up already, for example in Greece, Belgium, Moscow and Madison, Wisconsin, where reports of new abnormal karyotypes are collated and sent on to Dr Borgaonkar and Mr Rolling.

Their address is Division of Medical Genetics, Department of Medicine, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205.

anisotropy, and that this will tend to lie parallel to an applied magnetic field.

The directions of the axes of anisotropy in both A and B phases are expected to be strongly influenced by the container walls. The reason for this is particularly easy to appreciate in the case of the A phase, for it is intuitively obvious that, unless the orbital plane of a Cooper pair is parallel to the wall, there is a danger of one of the atoms bumping into the wall and so breaking the pair. Pair-breaking requires energy, and so the liquid reduces its total energy if it orients its pairs to rotate about axes perpendicular to the walls. Although the B phase is more complicated, here, too, depairing effects determine that the axis of anisotropy must be perpendicular to the wall. In fact, of course, it is not possible, even by bending the axis, to arrange that it should meet every wall of a given container at right angles unless there exist one or more singularities at which the local anisotropy axis is undefined, and these will presumably position themselves in such a way as to minimise the total energy of the liquid, contributing to a texture which is dependent on the shape of the container.

When a magnetic field acts upon the

liquid in a container of finite size, the texture must be even more complicated. One may, however, assume that the field, provided it is strong enough, will overcome the effect of the walls in determining the direction of the anisotropy axis at positions sufficiently far from the walls: there will be a characteristic distance r_c , dependent on field and temperature, within which the anisotropy direction moves from a wall-dominated to a field-dominated situation. Brinkman *et al.* calculated r_c for the B phase on the assumption of a Ballhau-Werthamer state and found that for $T \ll T_c$ it should be about $10/B_0$ mm with the magnetic field B_0 in mT or, in other words, comparable with the typical dimensions of a pickup coil for low field NMR. This implies that over a significant region of the sample the anisotropy axis will not be exactly parallel to the magnetic field, which will have the consequence of locally raising the frequency at which resonance occurs. The net effect is therefore an asymmetric broadening of the NMR resonance line towards higher frequencies, a broadening which should have a strong negative dependence on the magnitude of the applied magnetic field.

A field-dependent broadening of the

resonance is precisely what the Helsinki group has observed in the B phase, and although they have apparently not been able to check the detailed lineshape with that expected, the magnitude of the broadening seems to be in reasonable quantitative agreement with prediction. It was noted however, that the integrated NMR absorption was significantly lower than the calculated value. NMR measurements were also made on ^3He in the interstices of fine platinum powder, and it was observed that for small fields the signal broadened and disappeared rapidly as T was reduced below the transition temperature. This again is consistent with the picture of Brinkman *et al.* the liquid in each void will have its anisotropy axis determined almost entirely by wall effects because the void dimensions are less than r_c , so that the liquid takes up a domain-like structure with each domain in a different orientation relative to the applied magnetic field. The resonant frequency for each domain is therefore different so that, for the system as a whole, no resonance is seen.

Taking account of the discrepant behaviour of the integrated NMR absorption, and also in view of some earlier measurements of the static magnetic susceptibility, some doubt must inevitably remain as to whether $^3\text{He-B}$ is really in the Ballhau-Werthamer state. Further experiments, in particular measurement of the specific heat for $T \ll T_c$, will be required before the question can finally be settled. There seems little doubt, however, that both of the new liquid phases of ^3He enjoy the curious distinction of being anisotropic, magnetic superfluids which display textures when contained in finite vessels.

Earth wobble, day length and continental drift

from David W Hughes

Two well known facts have recently been combined in a rather fascinating way. The first is the period of Chandler's wobble, the second the secular decrease in the Earth's rotation period. The combination has been carried out by Cannon of York University, Toronto, Canada in a recent edition of *Physics of the Earth and Planetary Interiors* (9, 83, 1974).

The Earth is usually thought of as rotating once a day about an axis which passes through the North and South Poles. The picture is not quite so simple because the Earth is not a perfect globe but an imperfect oblate spheroid with unequal principal moments of inertia. The axis of symmetry of this oblate spheroid possesses

a degree of freedom known as wobble whereby this axis rotates about the space fixed axis of rotation. Now the wobble is very small, the Earth's pole moving around an imperfect circle of diameter about 14 m, equivalent to a 5 s arc axis movement. It can, however, be measured easily by observing carefully the passage of stars across the zenith at an observatory. This gives the colatitude of the observatory to about 0.01 s arc and the pole of the Earth can then be located to 0.3 m.

The Earth responds to the wobble excitation like a damped harmonic oscillator. Spectral analysis of the wobble data shows that part of the variation has a period of exactly one year—driven by the annual forces resulting from the seasonal redistribution of atmospheric mass, water vapour, snow and ice. The remainder of the data has periods ranging from 13 to 15 months, peaking at 428 d—this being known as the Chandler resonance. The length of the year (that is, the frequency of the annual driving force) has remained constant over geological time, whereas the Chandler resonance frequency has monotonically decreased due to the continual loss of terrestrial rotational energy by tidal interaction with the Moon.

Because of the effects of tidal friction on the dynamics of the Earth-Moon system, angular momentum from the rotation of the Earth is transferred to the orbital motion of the Moon. The day is lengthening by about 2.3×10^{-4} seconds each century and consequently the Moon moves further away, the semi-major axis of its orbit increasing by about 4 cm per year. So some time in the past the annual driving force passed through a resonance with the Chandler frequency, resulting in a large-amplitude wobble and during this resonance period geophysically significant amounts of solar energy (the Sun providing the motive power for the annual wobble) were dissipated in the upper mantle.

Resonant conditions would last throughout the time taken for the secular decrease of the Earth's rotation rate to scan the Chandler spectral band. This time interval depends on the rate of decrease of the Earth's angular velocity and on the specific dissipation of the oscillation energy in the Earth's crust. Cannon finds that resonance occurred some time between 242 and 129 million years ago, the mean estimate being 185 Myr ago. It lasted for around 5 to 25 million years. The total energy dissipated during this resonance comes to about 10^{33} erg, of the order of 10^{26} erg yr⁻¹. Considering the variation of specific dissipation with depth Cannon concludes that during this resonance most of the wobble energy was dissipated in the region of

the low velocity zone in the upper mantle, leading to a temperature increase of between 1 K and 10 K. As viscosity is dependent on the exponential of the temperature a 1 K rise causes a 5% decrease in viscosity, a 10 K rise decreasing the viscosity by 50%.

Cannon then goes on to speculate that the Chandler wobble resonance triggered continental drift, the decrease in viscosity enabling the continents to slide on the low velocity zone. Radiometric geological dating has shown that the greater part of the super-continent remained intact for as long as 2,000 Myr before the onset of continental drift. The epoch of the drift onset is thought to be 180–200 Myr ago, agreeing with the time of resonance. Also the Chandler annual resonance is energetically sufficient.

Drift in interference filters

from John Walker

INTERFERENCE filters are used a great deal in optical and spectroscopic instrumentation to isolate narrow regions of the spectrum. That is, they transmit a few selected wavelengths of light, and reflect the rest. One of their drawbacks is that the passband (the region of transmission) tends to shift in wavelength as the filter ages, which can be awkward in some applications. For example, a filter with a passband 0.6 nm wide, centred at 656.3 nm, was required for the H alpha telescope in the Skylab satellite (to study hydrogen in space by means of the H alpha spectral line). Obviously, even a small shift in such a filter would make it useless.

The programme of research which produced the stable filters used in Skylab is reported in a recent publication (Title *et al.*, *Applied Optics*, 13, 2675, 1974). These workers developed a dye laser and monochromator test system which could measure the transmission of the filters and detect the size and position of any defects. Although previous studies had indicated that heat treatment and humidity could cause drift, they found that ten weeks in a 100% humidity atmosphere had no effect on the filters. (One suspects that a longer test period might have caused some changes.) Heat was however found to cause drift.

To stabilise filters the manufacturer bakes them for a few hours at 100 °C. Subsequent storage at temperatures below 38 °C resulted in an average drift of the passband of 0.05 nm per year, but this increased to 2.5 nm above 80 °C, according to Title *et al.* A later set of filters, baked for much longer periods, showed no drift at all at 38 °C, a result in line with earlier work. They

were therefore used in Skylab.

An unexpected observation was that illumination also affected the filters' characteristics, and in a second paper (Title *et al.*, *Applied Optics*, 13, 2680, 1974) Title studied the phenomenon in more detail. A filter which had been exposed to solar radiation showed a drift of the passband towards shorter wavelengths. The transmission profile (as a function of wavelength) also changed, from approximately rectangular to triangular. Tests indicated that solar radiation at about 390 nm was responsible, and when a prefilter was used to cut it out the drift was eliminated. Wavelengths below 340 nm and above 500 nm did not cause any drift. Further experiments showed that longer baking times, which had stopped the 'ageing' drift, made no difference to the illumination effects.

An interference filter consists of alternate thin films of dielectrics of low and high refractive index, in this case cryolite and zinc sulphide. It is in fact a type of Fabry-Perot interferometer. Since zinc sulphide forms the interferometer cavity, and since it absorbs light at wavelengths below 500 nm whereas cryolite does not, the probability was that it rather than the cryolite was being affected by the illumination. This was confirmed by computer calculations, which showed that a decrease in the optical thickness of the zinc sulphide would not only shift the passband in the required direction, but would also result in a triangular profile, as observed.

Title did not determine whether the decrease in optical thickness was caused by a decrease in physical thickness or by a change in absorption coefficient of the zinc sulphide. Earlier work (Schneider and Rauber, *Solid State Commun.*, 5, 779, 1967, and Leutwein, Rauber and Schneider, *Solid State Commun.*, 5, 783, 1967) suggests the latter. These workers studied the optical properties and electron spin resonance of zinc sulphide crystals. Specimens which had been annealed in molten zinc showed a purple colouration, due to absorption bands at 430 and 545 nm. The colouration was enhanced by ultraviolet illumination at 355 nm, with an accompanying reduction in an absorption band at that wavelength. This is evidently the process occurring in the interference filters. Leutwein *et al.* also observed that the effect was reversible. The 355 nm absorption band was restored, and the other two eliminated, by illumination at 436 nm or by heating to 300 °C in the dark. The changes were accompanied by photoconductivity. Obviously there are two point defects in the zinc sulphide which are exchanging electrons through the conduction band. One of them, responsible for the 430 and

545 nm bands, seems to be the sulphur vacancy. The other, which causes the 355 nm absorption, was not identified. The presence of halogen or aluminium impurities also affected the spectra observed.

It therefore seems that illumination-drifted filters might be restored to their original condition by suitable illumination and/or heat treatment. Furthermore, it may be possible, by controlling the impurity content of the zinc sulphide, to make interference filters whose passband does not drift under illumination.

Crack theory developed

from Peter J. Smith

THE dilatancy model for earthquake precursors is one which in general terms attracts wide support. But as O'Connell and Budiansky (*J. Geophys. Res.*, **79**, 5412, 1974) point out, there are disagreements over detail which reveal that understanding is far from complete. For example, Nur (*Bull. Seismol. Soc. Am.*, **62**, 1217, 1972) proposed that the precursory decrease in P wave-S wave velocity ratio (V_P/V_S) is due to the opening of new dry cracks in the focal zone of an earthquake, whereas Whitcomb *et al.* (*Science*, **180**, 632, 1973) noted that vaporising the fluid in saturated cracks would have the same effect. Perhaps it would be wrong to describe this as a disagreement, since it is doubtful whether either party would man the barricades to support their respective viewpoints, suffice it to say that here we have two possible mechanisms for the same phenomenon and that it is necessary to determine which, if either (and if not both), actually obtains.

What does seem to be agreed by most people is that the elastic responses of rocks in an earthquake zone are critically dependent upon the presence of internal cracks and pores and whether they are wet or dry. Yet even here the dilatancy models currently available may be incorrect in detail. As O'Connell and Budiansky again point out, current theoretical analyses of the effect of cracks on the elastic properties of solids apply only to systems in which the cracks are assumed to be so far apart that the effect of each crack on the properties of the uncracked material may be determined independently. This was the basis upon which Walsh (*J. Geophys. Res.*, **74**, 4333, 1969), for example, assessed the influence of both dry and saturated cracks, and his analysis was derived, in turn, from the earlier work of Wu (*Int. J. Solids Struct.*, **2**, 1, 1966) and Eshelby (*Proc. R. Soc.*, **A241**, 376, 1957). Actual crack densities in rocks

have seldom been measured or estimated. So are dilatancy models involving low crack densities really valid?

To find out, O'Connell and Budiansky have carried out a new theoretical analysis which puts no initial restriction on the crack density and thus takes into account interactions between cracks. This freedom turns out to be critical. The model itself consists of a solid containing very thin randomly oriented ellipsoidal cracks which may be wholly dry, wholly saturated or a mixture of both. When the elastic properties predicted from the model are compared with the experimental data obtained by Nur and Simmons (*Earth planet. Sci. Lett.*, **7**, 183, 1969), who measured wave velocities in both dry and saturated rock samples at various pressures up to 3 kbar, it becomes quite clear that consistency can only be achieved by relatively high crack densities. For example, at zero pressure dry Westerly granite has a crack density of 0.25, which corresponds to one crack of diameter 12 units per unit volume (for example, one crack with a diameter of 12 mm mm⁻³). The corresponding figures for other dry rocks measured by Nur and Simmons range from 0.15 to 0.6, while in its wet state the Casco granite has a crack density as high as 0.7 (dry 0.4). Thus, all the rocks are extensively cracked and hence not strictly amenable to any theoretical treatment which presumes dilute crack concentrations.

A similar comparison is possible between the characteristics of the O'Connell-Budiansky model and the premonitory behaviour of the rocks in the region of the San Fernando earthquake of 1971—with equally interesting results. As Whitcomb *et al.* have reported, the seismic velocity ratio V_P/V_S decreased from its normal value

some 3–4 years before the San Fernando event and then gradually increased to its initial value just before the shock occurred. The original discovery of this effect was based on small earthquakes which preceded the main San Fernando shock in what was later seen to be the aftershock area and which were recorded at two stations on the same side of the aftershock zone. Subsequent work has shown that a similar result is obtained for small earthquakes occurring well outside the limits of the aftershock area but measured at two stations which have the aftershock zone between them. In other words, precursory changes in V_P/V_S are observed irrespective of whether the waves used to measure V_P and V_S pass through the main shock's epicentral zone or not.

In terms of the O'Connell-Budiansky model, however, the gross similarity in V_P/V_S behaviour does not entirely extend to the physical mechanism behind the variations. Outside the San Fernando epicentral region (original data recorded at stations on the same side of the region), the crack density before the V_P/V_S decrease lay in the range 0.2–0.3 and the cracks were predominantly saturated. Then during the V_P/V_S decrease in 1967 the crack density decreased marginally and the fluid in the cracks vaporised, which is consistent with the interpretation made originally by Whitcomb *et al.* But during the subsequent increase in V_P/V_S the crack density decreased much more noticeably to 0.15 and the cracks resaturated. This reduction in crack density is inconsistent with increased dilatancy upon resaturation, and implies instead a relaxation of strain which allows some cracks to close completely and the rest to relax sufficiently to eliminate the vapour

Getting closer to prediction

from Peter J. Smith

THE United States Geological Survey claims that "significant progress" was made towards earthquake prediction when scientists at the National Center for Earthquake Research in California managed to anticipate a moderate shock which took place on November 28 last year. This event, which had a magnitude of 5.2, occurred between the San Andreas and Calaveras faults about 16 km north of Hollister, California.

Prediction was based largely on precursory deformation of the Earth's crust and changes in the magnetic field. Crustal tilting was first observed about 4 weeks before the earthquake at two locations near what was to be the epicentre. But a "dramatic anomaly"

in the geomagnetic field in the epicentral region was spotted about 6 weeks ahead. Later analysis of recorded seismic data showed that premonitory variations in seismic wave velocity had also occurred.

According to the survey's director, Dr V. E. McKelvey, this is the first time that such a variety of precursory phenomena has been observed for a single earthquake in the United States. He warned, however, that this success should not be taken to imply that routine prediction for public safety planning is now possible. Significantly, he also pointed out that much still needs to be learned about how successful prediction could be used most effectively in reducing hazards.

phase within them. Inside the epicentral region (later data recorded at stations on opposite sides of the region), the pre-1967 crack density was slightly higher than outside but again the cracks were mostly saturated. And again the V_P/V_S decrease was accompanied by a decrease, albeit rather more marked, in crack density. But thereafter the picture changed. The subsequent increase in V_P/V_S was again related to resaturation but was now accompanied by an increase in crack density.

In summary, then, there are significant differences in the precursory processes inside and outside the immediate epicentral zone. Close to the main shock area the sequence is dilatancy-resaturation-dilatancy, whereas further away the sequence becomes dilatancy-resaturation-relaxation. Extensive cracking is common to both regions, however, and extends over a much wider zone than some workers have previously supposed. And again contrary to some previous views, the observed decrease in V_P/V_S is not due to the formation of new cracks but to a change from saturated to dry cracks. Indeed, changes in the saturation state of the cracks are apparently more important on the whole than changes in crack numbers.

Opening up the Universe

from P. C. W. Davies

MOST cosmologists now accept that the Universe began with a bang. But how will it end? The question has been of long-standing interest to both theologians and scientists, though the former have enjoyed greater success in producing answers. In recent months, however, evidence has been accumulating from diverse astronomical sources which consistently points toward a definite scenario for the future of the Universe. Although there is no question of a unanimous verdict at this stage, a movement of opinion among the pundits is becoming perceptible.

All discussion of this matter takes place within the context of the standard model for the Universe. In this standard model, the Universe moves in compliance with Einstein's general theory of relativity. This motion is visible to us as a general pattern of expansion, and because of the apparent large-scale homogeneity and isotropy, this expansion is assumed to be everywhere uniform.

If Einstein's equations are solved for such a uniform model universe they yield a two-parameter family of motions. All of these solutions predict that the expansion began a few billion years ago, when the Universe was in a

very dense condition. The onset of the expansion, expected to be very hot, is the big bang. The past history of the Universe is therefore, in broad outline, fairly unambiguous according to this theory.

As regards the future motion of the cosmos, all the solutions predict a gradual decrease in the expansion rate. Where they differ is in whether the decrease is strong enough to arrest the expansion and bring about recontraction, with the Universe falling back on itself to end up in a bang much like the one from which it originated. The alternative is for the expansion to continue for ever, with the Universe slowly sinking into thermodynamic equilibrium, after which little of significance will occur.

In principle it is easy to decide between these alternatives. Observations of the rate of recession of distant galaxies, seen as they were in the remote past, should indicate how the expansion rate has slowed since then. Alternatively, measurements of the present energy density in the Universe enables the gravitating effect to be calculated (through the general theory of relativity) as to how vigorously this gravitation is slowing the Universe down.

In practice, both types of observation are difficult to perform and complicated by many contentious side-issues. Now a paper has appeared in the *Astrophysical Journal* (194, 543, 1975) by Gott and Gunn from Caltech and Schramm and Tinsley from the University of Texas in which many of the observations and their theoretical ramifications are examined in detail. Gott *et al.* opt for an ever-expanding (or open) universe. Some of the arguments they use were presented by Gunn at the Seventh Texas Symposium on Relativistic Astrophysics (see the report from John Faulkner, *Nature*, 253, 231, 1975).

The authors parameterise their models in terms of the Hubble parameter H_0 (expansion rate at present epoch) and Ω , the ratio of the observed density of energy to the critical density required to collapse the Universe. For an ever expanding Universe, $\Omega \leq 1$. Their figure 1 shows the constraints obtained in their paper on these parameters.

Although H_0 may be measured directly ($30 < H_0 < 120 \text{ km s}^{-1} \text{ Mpc}^{-1}$) the age of the Universe, t_0 (8 to 18 billion years), is a more severe constraint. A direct estimation of the deceleration is complicated by evolutionary effects in both galaxies and QSOs, which tend to result in an overestimation of the deceleration parameter, $q_0 (= \Omega/2)$. To play safe an upper limit of 2 is placed on this parameter.

In contrast, the density (Ω) measurements tend to be underestimates, first because we only see the luminous matter in the Universe (stars, gas) and second because energy density may reside in the form of very low energy radiation (gravitons, neutrinos). Various methods for estimating Ω are critically described in the paper. Three independent estimates of the relative density of galaxies alone (denoted Ω^*) are used to obtain a value 0.05 ± 0.01 , and various arguments reviewed as to why any intergalactic matter would not be sufficient to give $\Omega > 1$.

In addition, a mention is made of recent theoretical work on the production of deuterium by nucleosynthesis in the hot big bang. The fraction of deuterium produced (D/H or ratio of deuterium to hydrogen) turns out to be very sensitive to the present energy density of the Universe. Using the results of measurements of galactic deuterium abundance, it is concluded that remarkably narrow ranges of Ω and H_0 are permitted in which $0.05 < \Omega < 0.09$ and $49 < H_0 < 65 \text{ km s}^{-1} \text{ Mpc}^{-1}$, predicting an ever-expanding Universe by a wide margin. The possibility of galactic deuterium production and nonstandard big bang physics is briefly reviewed.

The authors conclude that the density of the Universe is low, $\Omega \sim 0.06 \pm 0.02$, and a recontraction is ruled out. The most persuasive part of their argument is the fact that an ever-expanding Universe follows consistently from all the different sources of data, whereas to produce a recontracting model, a number of *ad hoc* assumptions are necessary. It is always possible to invoke exotic processes in the big bang, or to conjecture that most of the mass of the Universe is in the form of undetectable gravitational waves or black holes. But such conjectures are extremely hard to falsify with current technology, and seem somewhat contrived.

If Gott *et al.* are right, then instead of the Universe going out in a blaze of glory by recontraction, collapse and final cremation, it is doomed to everlasting frozen stagnation when the stars go out in a few dozen billion years.

Erratum

In the article "Chilling Statistics on Cyprus" by Peter J. Smith (*Nature*, 253, 500, 1975) magnetic vectors are mentioned in the last sentence of the fourth paragraph. This is incorrect and the sentence should read "In other words, on each side of the intrusion zone the chilled margins will all lie in the same direction (they will all be 'one way') and the degree of 'one way chilling' will be 100%."

articles

Reconnaissance Rb/Sr isochron study in the Bergen Arc System and regional implications

B. A. Sturt & O. Skarpenes

Geologisk Institutt, Avd. A, Universitetet i Bergen, Joach Friesgt 1, 5000 Bergen, Norway

A. T. Ohanian & I. R. Pringle

Department of Geodesy and Geophysics, Madingley Rise, Madingley Road, Cambridge, UK

On the basis of reconnaissance geochronological investigations, and the preliminary results of the reinvestigation of the tectono/metamorphic patterns of the Bergen Arc System it is possible to present a series of results which help to clarify the relationships of the rock units involved in this system. These results fundamentally affect the interpretation of the Bergen Arc System in Caledonian reconstructions of the geology of Western Norway.

Arc system This isochron age fits into the general pattern of the Svecofennian age previously recorded in the Baltic Shield⁶, and conforms with both the pattern of Svecofennian ages in the Nordland district⁷ and recent determinations from the basal/gneiss region in the Kristiansund area (Table 2). It also corresponds to the first Laxfordian metamorphism (LM 1) of the Scottish Lewisian⁹. In their original memoir Kolderup and Kolderup³ drew attention to gneissic rocks in

THE rocks of the Bergen Arc System consist of a series of arcuate belts both of Lower Palaeozoic metasediments and metavolcanics and of gneisses including migmatites and the anorthositic rocks of the Bergen-Jotun kindred¹⁻³ (Fig. 1). The age relationships of the various members of the arc system have been a matter of debate and various models have been proposed to explain them. Kolderup and Kolderup³ concluded that all the arc rocks east of the Øygardens gneiss area were of Caledonian development, a thesis supported by Hernes⁴ as recently as 1967. He further concluded that the Bergen Arcs represent a continuous stratigraphical sequence from Precambrian gneisses through late Precambrian metasediments and migmatites (The Minor Bergen Arc and Ulrikens Gneiss), late Precambrian metavolcanics (the anorthosites and associated rocks) into fossiliferous Lower Palaeozoic rocks (the Major Bergen Arc). Hernes supports this proposal by stating that the arc sequence can be correlated with a corresponding sequence in the Møre area. But Kvale⁵, following Reusch¹ and Werenskiöld², was convinced that the anorthositic and associated gneissic rocks represented an allochthonous thrust unit which overlies and separates the Major and Minor Bergen Arcs with their sequence of Lower Palaeozoic metamorphic rocks. Recent field and geochronological studies support Kvale's proposition, though the pattern of thrust tectonics is more complex than he then envisaged.

This account deals with a limited section of the arc system from the western basement gneisses of Sotra to the rocks of the anorthosite complex.

Øygarden region

The basement of the Sotra (Øygarden) region is represented by a series of granitic, granodioritic and tonalitic gneisses with amphibolites. Field studies show that these rocks have undergone several phases of reworking, under amphibolite facies conditions, that involve at least two stages of anatexis mobilisation. Several localities were sampled in this basement region and quartzo-feldspathic gneisses from the north of Sotra give an Rb/Sr isochron of $1,750 \pm 60$ Myr (Table 1), which represents the oldest age yet obtained from the basement to the Bergen

Fig. 1 Generalised geological map of the Bergen Arc System. Numbers refer to data given in Tables 1 and 4 and Fig. 2.

Table 1 Rb/Sr whole rock isochron ages from the Bergen Arc region

Rock type	Locality	Isochron (Myr)	Initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio (IR)	Source
1 Quartzofeldspathic gneisses	North Sotra	$1,750 \pm 60$	0.7015 ± 0.0020	This study
2 Partially retrograded quartzofeldspathic granulite	Fosnøy	1,775	0.704	Preliminary data
3 Anatectic granite	Sandviken, Bergen	$1,440 \pm 100$	0.7048 ± 0.0026	This study
4 Granite-gneiss	Selsta, Sotra	$1,024 \pm 85$	0.711 ± 0.005	This study
5 Foliated quartz-syenite	Ekrhovda, Sotra	$1,042 \pm 92$	0.718 ± 0.002	This study
6 Mangerite	Manger	$1,064 \pm 24$	0.7030 ± 0.0017	ref 19
7 Fine-grained granite dyke (boudin)	Telåvåg,	800 ± 14	0.731 ± 0.002	This study
8 Intrusive granite veins	Bjørndalstre, Laksevag	890 ± 150	0.730 ± 0.007	This study
9 Medium grained granite	Ekrhovda, Soltra	473 ± 31	0.754 ± 0.002	This study
10 Fana granite	Fana	453 ± 50	0.7063 ± 0.0037	ref 15
11 Rhyolite	Kattnakken, Stord	455 ± 5	0.7071 ± 0.0018	ref 16

the south of Sotra which have the mineralogy of quartzofeldspathic granulites, in the northern Sotra area relict granulite facies assemblages are found in several localities within boudins and show varying degrees of degradation to amphibolite facies. The low initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratio for this 1,750 Myr isochron suggests that this may be an original age rather than a metamorphic age. But on the basis of one isochron all that can be said is that this represents a minimum age for the gneisses, and that the granulite facies relicts could possibly indicate an older event.

In the central part of Sotra and extending onto the mainland at Løvestakken is a later zone of amphibolite facies foliation reactivation. A series of samples were collected from this zone both of the reworked gneisses and of leucocratic dykes and veins cutting them (Table 1). The results of the Rb/Sr isochron study (Tables 1 and 4, Fig. 2) yield the following results: (1) Granitic gneisses from Selsta give an isochron age of $1,024 \pm 85$ Myr and three biotite whole-rock pairs give respectively 598 Myr, 530 Myr, and 402 Myr. (2) A foliated quartz-syenite sheet intruding augen gneisses at Ekrhovda gives a whole-rock isochron at $1,042 \pm 92$ Myr and K-feldspar/whole rock ages of 546 Myr and 550 Myr. (3) A boudined highly radiogenic granite dyke, intrusive into these gneisses at Telåvåg yields a 'two-point' age of 800 ± 14 Myr. (4) Granite veins intruding foliated amphibolites at Bjørndalstre yield a whole-rock isochron age of 890 ± 150 Myr. (5) A boudined dyke of medium grained granite from Ekrhovda yielded a whole-rock isochron of 473 ± 31 Myr, with two biotite whole-rock ages of 398 Myr and 395 Myr.

It is concluded that this zone of structural/metamorphic reworking represents localised effects of Grenville (Sveco-Norwegian) reactivation of the older basement complex. Indeed the two isochron results at 1,024 Myr and 1,042 Myr, with relatively high initial $^{87}\text{Sr}/^{86}\text{Sr}$ ratios, conform well with the patterns obtained from Telemark^{13,14} and other west coast regions to the south which lie in the main zone of Grenville regeneration of the Southern Norwegian basement. Similar ages are seen in the nappe areas and the north west gneiss region (Table 3). The 890 and 800 Myr isochrons were determined on later minor granitic intrusions emplaced into this zone after the main Grenville reworking had ceased and again may be compared with similar intrusions from Telemark¹³. They are both now boudinaged, but this is likely to be an effect of Caledonian strains in the area. The youngest isochron age of 473 ± 31 Myr

from a boudinaged dyke is almost certainly an intrusive age and coincides closely with an isochron age of 453 ± 50 Myr obtained by Brueckner¹⁵ from the Fana granite and an isochron age of 455 ± 5 Myr for rhyolitic rocks¹⁶ in the Lower Palaeozoic volcanic complex of the island of Stord, south of Bergen (Table 1, Fig. 2). The deformation of this dyke occurred during the late Caledonian reworking of the basement complex. The Øygarden gneisses were regarded by Kolderup and Kolderup³ as being of Precambrian age, a view restated by others^{4,5}, and indeed indicated from K/Ar determinations¹⁷. The results of the present study abundantly confirm this view.

Ulriken and Manger region

The basement gneisses of the Øygarden area are structurally overlain by the rocks of the Minor Bergen Arc which mainly comprise metasedimentary and meta-igneous rocks of supposed Lower Palaeozoic age^{3,5}, although the Minor Bergen Arc also includes a number of zones of gneissic rocks which have strongly mylonitic fabrics and possibly represent imbricated slices of the underlying basement. As yet no geochronological studies have been carried out on these rocks.

Structurally above the rocks of the Minor Bergen Arc there are the migmatitic gneisses of the Ulriken's gneiss zone, separated from the former by a considerable thickness of repeated blastomylonites. These gneisses have previously been described as Caledonian migmatites³ with associated metasediments. Recent mapping (A. Thon, and T. Sylvester, personal communication) shows that this is a highly complex zone of gneissic rocks comprising at least three thrust units of migmatitic gneisses separated by zones of younger metasediments and blastomylonites. The migmatitic gneisses show a complex history of repeated migmatization separated by deformational phases and periods of emplacement of minor basic intrusives as dykes and sheets. To make a preliminary assessment of the age of these gneisses samples were collected from a series of well-marked anatectic veins which cut foliated basic sheets. The basic sheets cut earlier migmatitic structures which contain deformed basic schlieren and quartzofeldspathic vein material, thus showing that the sampled veins represent a late stage in the tectono-metamorphic development of the gneisses. The result of the first Rb/Sr isochron study from these rocks yields an age of $1,440 \pm 100$ Myr for the late anatectic veins, and shows clearly that the gneisses of the Ulriken's gneiss zone are of Precambrian age. The age of this anatexial-metamorphic event may conform with a recent result of $1,550 \pm 100$ Myr for the overthrust gneisses in the Hardangervidda area^{18,21} and would seem to correspond to the second Laxfordian metamorphism (LM 2) in the Scottish Lewisian⁹. The possibility that the gneisses of the Ulriken's gneiss zone are considerably older than this must not be ruled out, especially as the isochron of 1,440 Myr was obtained on late anatectic veins which postdate an involved sequence of metamorphic development in the gneisses.

The gneisses of the Ulriken's gneiss zone are separated from the structurally overlying rocks of the anorthosite association by a marked development of blastomylonitic rocks and the two zones appear to represent different structural-metamorphic units, as indeed was indicated by earlier workers in the region^{1-3,5}. The results of an Rb/Sr isochron study of mangerites,

from the type area at Manger, have already been published¹⁹, and show an isochron age of 1,064±24 Myr which was concluded to represent the age of granulite facies metamorphism of these rocks. This seems to show a Grenville (Sveco-Norwegian) age of metamorphism and fits well determinations made on mangerites in the Egersund region²⁰ both in terms of whole-rock Rb/Sr isochron studies and U/Pb on zircons. The rocks of the anorthosite association have been correlated with those of the Jotun Nappe (as part of the Bergen-Jotun Kindred^{3,5}). No results are available from equivalent rocks in the Jotun Nappe,

but Priem²² has dated the Hestbrepiggen Granite, in this nappe, at 1,033±37 Myr. The work of Banham²³ shows that this granite has undergone deformation and metamorphism. Two K/Ar mineral ages are available on feldspars from pyroxene gneisses at 1,280±30 and 1,020±40 from the north-western part of the Jotun Nappe²⁴. With the limited data available it is only possible to suggest the coeval nature of the metamorphism in the two situations. Two Rb/Sr biotite whole-rock determinations made on the mangerites from Manger and these gives ages of 407 and 356 Myr.

Fosnøy region

Recent mapping of the Fosnøy region in the northern part of Kolderup and Kolderup's Anorthosite association³ shows the geological situation of these rocks is much more complex than has previously been envisaged. Rocks of the anorthosite association *per se* are separated from an amphibolite facies gneiss complex which includes migmatites, metasediments and metabasites, hereafter termed the 'Fosnøy gneiss complex' by clearly marked zones of blastomylonite and porphyroclastic gneiss up to 50 m thick. The structural relationships of the two rock complexes show an intricate folding of the interface including the blastomylonites, by at least two folding phases of presumed Caledonian age, the earliest of which has produced a large sub-isoclinal fold of the contact. The amphibolite facies rocks of the Fosnøy gneiss complex represent strongly downgraded granulite facies rocks. Relicts of the granulite

Table 4 Analytical data for new dates reported. Experimental uncertainties²⁰ are taken as 1.5% and 0.15% for the ⁸⁷Rb/⁸⁶Sr and ⁸⁷Sr/⁸⁶Si ratios respectively (⁸⁷Rb/⁸⁶Sr ratios for all minerals and whole rock samples from Fosnøy, Sandviken and Manger were determined by isotope dilution analysis, the others by XRF analysis)

facies assemblages are variably preserved. The first amphibolite facies foliation in these rocks has been subjected to three phases of folding before the emplacement of a set of granite aplite dykes which themselves predate the formation of the blastomylonites developed at the contact with the rocks of the anorthosite association.

To obtain an assessment of the age of the Fosnøy gneiss complex we collected samples from both the granulites and the aplite dykes mentioned above. Unfortunately both suites of samples have very low Rb/Sr ratios and the dykes in particular have a very small spread of these ratios. On the basis of preliminary results so far obtained from partially downgraded granulites, it is only possible to say that they are suggestive of an age of approximately 1,775 Myr. This approximate age corresponds with ages obtained for the older gneisses on Sotra (Table 1) and indicates them to be of Sveco-Fennian/Laxfordian (LM I) age. Whether or not this represents the age of granulite facies metamorphism or the amphibolite facies retrogression of the granulite facies rocks is not possible to say at this stage of the investigation.

Significance for the Bergen Arc System

The results of the present reconnaissance Rb/Sr isochron study of the western portion of the Bergen Arc System show a series of important results. First, the basement gneisses of the Øygarden are confirmed as being of Precambrian age, with minimum age approximately 1,750 Myr. This corresponds to the main Sveco-Fennian event of the Baltic Shield, though the presence of relicts of down-graded granulite facies assemblages in the rocks of Sotra suggest that this basement complex may be even older. The results further show that the basement of the Øygarden has been reworked during the Grenvillian (Sveco-Norwegian) event at 1,000–1,200 Myr and has subsequently been intruded by granitic dykes at around 800–900 Myr. These results demonstrate the complex sequence of deformational/metamorphic events which have occurred in the basement substrate of the Bergen Arc System before the Caledonian Orogeny. The results from the Ulriken gneiss complex, the Anorthosite association and the Fosnøy gneiss complex show that substantial parts of the thrust nappes overlying the Lower Palaeozoic schists of the Minor Bergen Arc represent overthrust masses of Precambrian basement rocks, and furthermore that they are probably derived from significantly different portions of the basement substrate to the Caledonides. The age of 473 ± 21 Myr for a late granitic dyke in the basement conforms with the age of other granitic activity, during Ordo-Silurian times, within the general region.

The mineral ages are metamorphic ages representing the effect of Caledonian reworking on the Precambrian rocks investigated. The group of mineral ages in the range of 500–590 Myr probably represents either an incompletely reset last event or incompletely reset ages related to the early Caledonian-Grampian event. The group around 400 Myr certainly seems to fit with the well documented late/end Silurian event recorded in most parts of the Caledonides, this is also the stage at which the major transport of the thrust nappes occurred. The latest age at 356 Myr may possibly reflect movements affecting the Devonian rocks to the north of the Bergen Arc region, but inference from one biotite age is only tentative.

Brueckner¹⁵, in reviewing the age patterns from Precambrian rocks in southern and western Norway, makes strong appeal to the lack of continuity of the Karelian-Laxfordian age province in this region, and suggests that there is a lack of fit between the Baltic and Greenland Shields across the continental best-fit reconstruction of Bullard *et al.* This is based on the lack of suitable age determinations in the 1,500–1,800 Myr range south of latitude 62° N in Norway. Since Brueckner's paper, however, several results within this range have been reported (Tables 1 and 2). There are several U/Pb zircon ages within this range^{8,20}, and also K/Ar ages for amphiboles and pyroxenes from the NW gneiss area^{26,27}. Thus it seems that there is considerably more continuity of the Ketilidian-Laxfordian age

province into western and south-western Norway than has previously been suggested¹⁵, though the age pattern has obviously been rendered more complex by the varying intensity of Grenvillian (Sveco-Norwegian) reworking.

On the basis of the Rb/Sr isochron ages at present available it is interesting to speculate on the possible form of the Grenville orogenic configuration in pre-Caledonian times in the North Atlantic region. Traditionally the Grenville-Sveco-Norwegian zone has been projected eastwards from Canada across Scotland into the southern part of Norway, swinging sharply into a NNW-SSE trend in south-eastern Norway and south-western Sweden^{7,28}. Evidence we present here, and other data¹⁵, shows that the effects of the Grenville-Sveco-Norwegian regeneration also affects basement gneisses in the north-west gneiss area of Western Norway (Table 3). The presence of Grenville-Sveco-Norwegian metamorphic ages in the thrust complexes of Western Norway (see also refs 12, 22), which are regarded as having been thrust from a north-westerly direction, poses the intriguing possibility that a major arm of the Grenville orogenic zone previously extended through the northern part of the North Atlantic passing between Greenland and Scandinavia. Several Rb/Sr isochron ages, in the general range 1,000–1,200 Myr have recently been established on the seaboard margins on either side of the northern North Atlantic area. The possibility of an isotopic event at approximately 1,200 Myr in northern Norway has been proposed recently for rocks from the Nasafjell window in Nordland⁷ and from the Lofoten Islands²⁹. In Western Finnmark an age of metamorphism of approximately 1,030 Myr has been indicated for gneisses within the Caledonian belt^{30,31}, and on the western side of the Caledonian orogene Rb/Sr isochrons, K/Ar mineral ages and U/Pb zircon ages in the range 1,060–1,194 Myr have recently been published^{32,33}, for westward thrust basement slices within the Caledonides of the Scoreby Sound region of East Greenland.

Though much more comprehensive geochronological work is obviously required to substantiate this proposition, it seems necessary at least to speculate on the possible presence of a northern arm of the Grenville orogenic zone extending between Greenland and Scandinavia more or less along the site of part of the subsequent Caledonian orogene. The patterns of published age determinations from the continental blocks of Greenland and Scandinavia indicate that the effects of such basement reactivation and metamorphism are restricted to the western seaboard of Scandinavia and within overthrust masses on the respective sides of the Caledonian orogene.

Missing link between Milankovitch and climate

G. J. Kukla

(CLIMAP) Lamont-Doherty Geological Observatory of Columbia University, Palisades, New York

A simple empirical model shows that Earth's surface temperature is most affected by seasonal change of irradiation in the interior of North America and Euroasia, and that the highest sensitivity to insolation is reached in the autumn. Past climates are explained by adjustment of the cryosphere to changes of insolation in early autumn.

It has been suggested that the gross changes in Pleistocene climate were controlled by variations in the Earth's orbit, often referred to as Milankovitch's mechanism¹⁻³. Radiometrically dated palaeoclimatic evidence strongly supports such a conclusion. The periodicity in the occurrence of gross cold and warm peaks during the past 150,000 yr matches that of the precession cycle⁴. The process affects only the seasonal and geographical distribution of the irradiation, yearly totals remaining constant. Surplus in one season is compensated by a deficit during the opposite one, surplus in one geographical area is compensated by simultaneous deficit in some other zone. If the mechanism influences climate, a sensitive area and/or season must exist in which heat budgets are modified by changes in incoming radiation to a larger extent than in the rest of the globe and/or during the rest of the year.

Climatologists of the Milankovitch school have seen such a zone in the high latitudes of the northern hemisphere where Pleistocene continental glaciers repeatedly developed and vanished. The sensitive season was considered to be summer because contemporary mountain glaciers would melt during warm dry summers but grow during the cool wet ones. Without further analysis, it was presumed that cool summers would result from lowered insolation and Milankovitch's tables³ as well as their modern counterparts^{5,6} were calculated as time series of zonal irradiation totals for summer half year (spring and summer) and winter half year (autumn and winter).

Today costly mathematical models are used to test the effects of Milankovitch's mechanism on climate^{7,8}. It seems appropriate, therefore, to check the assumption on the decisive climate forming role of summer and examine the geographical relationships of seasonally changing insolation and temperature with recently available weather data. My objective is to localise the area and season which is exceptionally sensitive to insolation change.

Basic assumptions

The ability of the atmosphere and ocean to store and redistribute energy makes an analysis of any local heat budget

rather complicated. We do not have sufficient knowledge and resources to attempt a complete study involving all the elements of the Earth's heat budget on a global scale.

But we can try to identify the sensitive areas and seasons as such, where and when the change in the local ground level irradiation is paralleled with least delay by the largest change in surface temperature.

This approach should be correct if two basic assumptions involved are correct, namely

(1) That the energy transformation at ground level is of primary importance in determining the climatic state, while the variations in direct solar heating of the atmosphere and in the escape of long wave radiation have only contributory effects on the ground level climate⁹.

Fig. 1 Mean monthly surface air temperatures (triangles) for the globe (G), Northern Hemisphere (NH) and Southern Hemisphere (SH) compared with extent of cryosphere T_0 (dotted line), snow and ice cover (full line), and Q_0 (heavy dots), Q_{200} (light dots), Q_{400} and Q_{600} areas (4 and 6 respectively). Also shown are seasonal changes in global R (reflection from snow and ice assuming cloudless days). The seasonal wave in mean global temperatures is controlled by the Northern Hemisphere and the mean global and NH temperatures inversely correlate with the extent of cryosphere.

Table 1 Monthly means* of Q , T , and S

	Globe			Northern Hemisphere			Southern Hemisphere		
	Q	T	S	Q	T	S	Q	T	S
	langley	$^{\circ}\text{C}$	10^6 km^2	langley	$^{\circ}\text{C}$	10^6 km^2	langley	$^{\circ}\text{C}$	10^6 km^2
	d^{-1}			d^{-1}			d^{-1}		
January	560	12.2	76	365	8.0	58.4	755	16.5	18
April	570	14.1	59	570	14.2	41.2	570	14.1	18
July	530	16.1	42	725	21.6	14.3	335	10.6	28
October	570	14.3	57	570	16.2	22.8	570	12.4	34
Mean	560	14.2	60	560	15.0	34.8	560	13.4	25

* Q , After Berland¹⁰, T , long term means after Shutz and Gates¹¹, satellite observed mean S areas covered for at least five consecutive days in the Northern Hemisphere during 1967-73 interval and in the Southern Hemisphere in 1968 (ref 14).

Fig 2 Rates of increase (positive values) and decrease (negative values) of S and Q_{200} areas through the year. Sensitivity index SI shows the proportion between ΔS and ΔQ_{200} after the formula $SI = (\Delta S / \Delta Q_{200}) \times 100$. High positive index indicates high sensitivity of climate to insolation change, as observed in the Northern Hemisphere from September through November. Q_{600} marks intervals where ΔQ_{200} was substituted in the formula by ΔQ_{600} . Dotted line through areas where ΔS or ΔQ approaches zero.

(2) That the atmospheric and oceanic circulation in general tends to smooth and compensate, rather than strengthen the geographic and temporal differences in the heating of the globe. Thus, the longer the delay between the local irradiation change and climatic response, the greater the influence of compensatory processes related to lateral heat transport, and the lower the sensitivity of local heat budget to the insolation input at any moment.

The QTS-1 model

QTS-1 is a highly simplified one-level global climate model in which heat transfer in the atmosphere and oceans as well as the hydrologic cycle are completely disregarded. It is named after the main recognised variables: ground level irradiation Q , surface air temperature T , and the area of snow and ice cover S . The 'instant' climate state in the model is defined by the mean surface air temperature T . Extensive parametrisation of empirical input data was used in the present first version of the model, QTS-1. Improved variants will be studied in the future.

The sources of input data and the way they were parametrised are as follows:

Q Daily totals of solar radiation incident upon the Earth's surface under cloudless sky, accounting for zonally averaged mean turbidity¹⁰. Units are langley d^{-1} , where 1 langley = 1 calorie cm^{-2} . Related measures are Q_0 , the area in million km^2 with no irradiation income, and Q_{200} , Q_{400} , and Q_{600} , the areas where irradiation is below 200, 400, and 600 langley d^{-1} respectively. Cloud effect on Q is omitted.

T Surface air temperature ($^{\circ}C$) (refs 11–13). T_0 is the area with temperatures below $0^{\circ}C$, corresponding roughly to the ground level extent of the cryosphere.

S Snow and ice covered area irrespective of snow density in million km^2 . Data from the northern hemisphere obtained from NOAA weekly maps of average snow and ice boundaries, all other data as listed in ref. 14. Only areas covered for more than five consecutive days are included. Though the reflectivity of snow fields as well as bare surfaces varies within a wide range, the establishment and disappearance of snow introduces by far the most striking seasonal change into surface albedo¹⁵.

R The parametrised measure of radiation (langley d^{-1}) reflected from snow and ice in excess of that which would be

reflected in the same situation by bare ground or ocean free of ice cover.

The principal advantage of the QTS-1 model with immobilised atmosphere and non-existent heat storage capacity is that local air surface temperatures are a function of instantaneous local irradiation and albedo only. Thus, solution of our problem, which is to locate the sensitive zone and season, can be found by determining where and when the observed real world behaviour most closely approaches the relationship anticipated in the model.

Interpretation of QTS variations

The observed data are in Table 1. The globe is warmest in July under low Q and coldest in January under high Q . The global mean temperature is not a direct function of global mean Q , and the seasonal Q wave is approximately symmetrical between the two hemispheres whereas the T wave is not.

Figure 1 shows the variation of global and hemispheric mean T compared to areal changes of T_0 , S , Q_0 , Q_{200} , and Q_{400} . The T_0 area closely approaches the S area, so that for the purpose of the present discussion, T_0 can be considered equal to S . There is an inverse relationship between the global T and S ; in a first order approximation, the global mean T and thus the global mean climatic state could be considered a function of S . The same relationship is valid for the Northern Hemisphere.

The seasonal wave of global T and S is shaped in agreement with the T and S waves in the Northern Hemisphere because of high seasonal contrast over the northern continents. Thus, the seasonal variation of temporal global climate states seems to be basically controlled by variations in snow and ice cover area in the Northern Hemisphere.

The fast global increase of S between September and November coincides with the buildup of snow and with the increase of Q_{200} area in the Northern Hemisphere, and with the sharp increase of R in the Southern Hemisphere, when the planet passes from low surface reflection (LSR) to high surface reflection (HSR) mode. Although the increase of S in the Northern Hemisphere is relatively fast and the decrease slow, the opposite seems to hold true for the Southern Hemisphere where the buildup of fields of pack ice is slowed down by the heat reserves in the ocean. The snow cover, once established with its high albedo and high specific heat required for melting has a self-perpetuating cooling effect on environment.

In Fig. 2 the rates of change in S and Q_{200} areas are plotted

Fig 3 Seasonally changing mean latitudinal position of the snowline (full black line) from October 1971, until January 1973, between $50^{\circ}E$ and $70^{\circ}E$ compared with long term mean surface air temperatures ($^{\circ}C$) (dotted lines, zone between $0^{\circ}C$ and $+2^{\circ}C$), and ground level cloud free insolation Q (langley d^{-1}) (stippled). From September through November the snowline and the $0^{\circ}C$ isotherm follow the 200 langley d^{-1} isotherm. First day of each month is marked.

Fig 4 Departure of the monthly mean area covered by snow and ice in the Northern Hemisphere in 1972 (cold anomaly) from 1968 levels

as a function of season. The ΔQ_{200} values are almost the same in both hemispheres whereas the ΔS is greatest in October and November in the Northern Hemisphere. The disintegration of snow fields in the Northern Hemisphere and pack ice in the Southern Hemisphere are substantially slower.

The bottom line in Fig 2 shows the sensitivity index (SI) which indicates the relationship between simultaneous ΔQ_{200} and ΔS . Index values are irrational and are not plotted (denoted by connecting dotted line) if ΔQ_{200} or ΔS approach zero. Large SI indicates that the rate of change of Q_{200} closely parallels that of the S areas and thus the high sensitivity of S to insolation change. The greatest SI for the globe (about 60), Northern Hemisphere (about 80) and the Southern Hemisphere (about 13) are reached simultaneously in October and November, identifying this interval as the sensitive season.

Changing mean latitudinal position of the snowline in the interior of the Euroasian continent and the corresponding T and Q values are shown in Fig 3. They were plotted for the meridional segment between 50° E and 70° E, which is composed mainly of lowland. The advancing snowline in autumn, together with the T_0 boundary, closely follow the isoline with irradiation $Q = 200$ langley d^{-1} .

In contrast, between March and June, during the poleward retreat of T_0 and S , the snowline move is substantially delayed relative to Q and the irradiation above the snowline steadily increases from 400 to about 800 langley d^{-1} . Thus, in the studied segment, a distinct seasonal asymmetry exists in the relationship of Q to S . The snowline essentially follows the irradiation drop in autumn but it is substantially delayed behind insolation rise in spring¹⁷.

Between September 1 and December 21 in the North American and Euroasian interiors, the Q at the snowline drops only by about 2 langley d^{-1} for each degree of latitude of snow fields southward advance. Q increases by about 15 langley d^{-1} (from 10–22) per degree of latitude of snowline retreat between March 1 and June 21. Similar measurements in the Southern Hemisphere give the Q departure at the advancing pack ice front as about 45 langley d^{-1} degree⁻¹. The greatest sensitivity of S to Q (and thus of climate to Q) is reached at the time when the snowline accurately follows the shifting insolation pattern resulting in zero change in Q over the snowline. The conditions observed during autumn in the interior of the continents of the northern hemisphere are closest to this situation.

Test against present weather variability

In the real world the surface temperature and reflectivity depend on a number of factors, many of them unrelated to local insolation. Thus, simple relationships anticipated in the model may not exist at all. On the contrary, feedbacks may exist strengthening the dependence.

• There are several ways the validity of tentative conclusions derived from the QTS-1 model could be tested. One is mathematical modelling which could be undertaken in the future. Others are various partial tests, using the present observed

short term fluctuations in meteorological variables. Such tests could include correlation of past snow cover history with annual temperatures. The present hypothesis would be supported if significantly high correlation was found between the years with relatively extensive snow cover in fall and the anomalously cold years. Satellite observations of snow as yet cover too little time to provide statistically significant tests. Available maps, however, include four relatively normal years (1967–70) and two anomalous cold years, 1971 and 1972. The atmosphere below the 500 mbar pressure level north of 15° N was 0.35° C cooler in 1972 than in 1968 (ref 18). So, at least for the northern hemisphere, the snow and ice cover extent of a 'normal' year could be compared with that corresponding to the anomalously cold year. Figure 4 demonstrates that the 1972 anomaly, as compared with 1968, was indeed characterised by significantly larger area of snow and ice on an annual average and by significantly earlier deposition of snow in autumn.

Test against palaeoclimatic history

If the continents in the northern high and mid-latitudes are the sensitive area, and the autumn is the sensitive season intercepting the extraterrestrial impulses, then the timing of the expected impact of Milankovitch's mechanism on this area and season should fit the radiometrically dated palaeoclimatic evidence.

Figure 5 shows the seasonal variation over the past 30,000 yr in energy flux at the top of the atmosphere in the plane facing the Sun, as a result of the Milankovitch mechanism. The September and October mean global irradiation on the top of the atmosphere peaked about 6,000 yr ago, reaching 725 langley d^{-1} and dropped to a minimum of 675 langley d^{-1} about 17,000 yr ago, with corresponding change of Q values.

It is well known from isotopically dated palaeoclimatic evidence that the highest postglacial surface temperatures were reached about 5,000–7,000 yr ago and that the most recent glacial culminated sometime between 15,000 and 19,000 yr ago¹⁹. In a first approximation the correlation can be extended to at least 150,000 yr BP simply by using conventional Milankovitch summer or winter half-year curves with timing shifted by 5,000 yr (ref 20).

Within the precision limits of radiometric dating the gross shape of palaeoclimate curves for the past 20,000 yr also correlates well with the irradiation levels in early autumn^{4,19,20}. This observation, even though not yet analysed quantitatively,

Fig 5 Irradiation at the top of the atmosphere in the plane perpendicular to solar rays during the past 30,000 yr, at the summer solstice (J), winter solstice (D), spring equinox (M) and autumn equinox (S). According to my QTS-1 model, the autumn irradiation, approximately represented by the S curve, controls the global extent of cryosphere and through it the climate.

lends substantial support to my hypothesis, which predicts delayed snow accumulation in the Northern Hemisphere under the high autumn irradiation 6, 28, 42, 55, 77, 101 and 122 thousand years ago with, by contrast, an early snow accumulation in the north and a late pack ice melting in the south under the low early fall irradiation 17, 36, 51, 67, 89, 111 and 134 thousand years ago. It could be speculated that the mechanism was less efficient during full glacial conditions in North America because of substantially reduced seasonal snow fields at the expense of permanent ice. The opposite holds true for Asia and Eastern Europe. So the North American subcontinent could have been less sensitive and Asia more sensitive to insolation change during a full glacial than they are today. Also the timing of the most sensitive interval may have shifted between August and November according to the varying surface properties of the Pleistocene continents.

Because the QTS-1 model does not recognise heat and water transfer in the atmosphere, the validity of the conclusions in the real world remains tentative. But my tentative results indicate that (1) the conventional assumption on summer half-year insolation in the northern hemisphere as linking Milankovitch's mechanism with climate through millenia long delay is probably invalid, (2) an accurate astronomical dating of gross Pleistocene climatic history is feasible since the climate probably adjusts to changing insolation patterns with negligible delay, (3) the long term outlook for natural climate development as predicted from the QTS-1 model is the perpetuation of oscillatory cooling for another 4,000 yr and (4) the heat balance developments in the inner parts of the

northern continents deserve the close attention of long-range weather forecasters. The sensitivity concept provides a plausible explanation of the 20,000-yr climate cycle and a new look at the mechanism of climatic variability. Nevertheless it is far from a complete theory of climate change and leaves unexplained the causes of the 10^6 yr Pleistocene glacial cycle as well as the causes of climatic variability on the time scales of millenia.

Darwinian evolution in the genealogy of haemoglobin

Morris Goodman & G. William Moore

Department of Anatomy, Wayne State University, Detroit, Michigan 48201

Genji Matsuda

Department of Biochemistry, Nagasaki University, School of Medicine, Nagasaki, Japan

Frequencies of mutations between reconstructed ancestor and descendant sequences of codons for metazoan globin chains show that natural selection guided protein evolution. Mutations which improved haemoglobin function were accepted at an accelerated rate in the first vertebrates. Rates decelerated after functional opportunities had been exploited.

THE differences between 55 contemporary globins with well analysed amino acid sequences¹⁻⁴⁷ have been used to deduce the genealogical tree shown in Fig. 1. Analysis of patterns of mutation between ancestors and descendants on this tree shows that natural selection improved the haemoglobin molecule and then preserved the improvements. Early evolution proceeded at a faster rate (mutational replacements per unit time) than later evolution. This can be shown to correlate with Darwinian theory by taking advantage of the identification of functional residues (Table 1) by Perutz and coworkers⁴⁸⁻⁵³. We have deduced that during the evolutionary transition of monomeric haemoglobin to a tetramer with a sigmoid oxygen equilibrium curve the residue positions which acquired cooperative functions changed more rapidly than other positions. Such a pattern cannot be explained by the theory of random fixation of

selectively neutral mutations⁵⁴, so called non-Darwinian evolution⁵⁵. It can be attributed, however, to positive selection for more optimal function.

Reconstruction of genealogy

A maximum parsimony approach^{56,57} was used to reconstruct the genealogy of the globin chains. According to the parsimony principle⁵⁸⁻⁶², the best genealogy requires the fewest possible nucleotide replacements. In such a genealogy the maximum number of sequence similarities is associated with common ancestry, and the minimum number with parallel and back changes.

A mathematically rigorous procedure reconstructs the most parsimonious ancestors for a given genealogy⁵⁶. There is no known method, short of an exhaustive search, for finding the most parsimonious genealogy. Thus we used an heuristic approach, in which an initial, unweighted pair-group cluster analysis⁶³ was improved repeatedly by a branch-swapping procedure⁵⁷. The search was extended by sliding portions of the globin alignment in order to further reduce the length (that is total number of nucleotide replacements) of the genealogy.

Regions in the genealogy in which few nodal points span long periods of time were underrepresented with respect to nucleotide replacements. Thus we compensated for lost

Fig 1 Globin genealogical tree Soybean¹, insect CTT-1 (Braunitzer, unpublished) and CTT-3 (ref 2) (*Chironomus thummi*), annelid (*Glycera dibranchiata*)³, mollusc (*Aplysia limacina*)⁴, *Petromyzon marinus*⁵, *Lampetra fluviatilis*⁶, myoglobin of kangaroo (*Megaleia rufa*)⁷, human⁸, horse⁹, sheep¹⁰, bovine¹¹, harbour seal (*Phoca vitulina*)¹², porpoise (*Phocaena phocaena*)¹³, dolphin (*Delphinus delphis*)¹⁴, sperm whale (*Physeter catodon*)¹⁵, β echidna (*Tachyglossus aculeatus*)¹⁶, β *Potorous tridactylus*¹⁷, β kangaroo (*Macropus giganteus*)¹⁸, γ human¹⁹, β dog²⁰, β mouse C57BL²¹, β Japanese macaque (*Macaca fuscata*)²², β rhesus (*Macaca mulatta*)²³, β *Cercopithecus aethiops*²⁴, β langur (*Presbytis entellus*)²⁵, β human²⁶, β *Cebus apella*²⁷, β slow loris (*Nycticebus coucang*)²⁸, α carp (*Cyprinus carpio*)²⁹, α *Catostomus clarkii*³⁰, α dog³¹, α mouse C57BL³², α slow loris (*Nycticebus coucang*)³³, α *Cebus apella*³⁴, α *Ateles geoffroyi*³⁵, α human³⁶, α langur (*Presbytis entellus*)³⁷, α *Cercopithecus aethiops*³⁸ and α rhesus (*Macaca mulatta*)³⁹. Link lengths are the numbers of nucleotide replacements between adjacent ancestor and descendant sequences and are italicised when our augmentation algorithm corrects for superimposed replacements. Original and corresponding augmented link lengths are as follows: 0-0, 1-1, 2-2, 3-3, 4-4, 5-5, 6-8, 7-9, 8-10, 9-11, 10-15, 11-16, 12-17, 14-20, 15-21, 16-22, 18-29, 20-43, 21-44, 24-47, 27-50, 28-51, 29-52, 31-54, 32-55, 34-58, 36-66, 50-93, 59-115, 63-136, 64-137, 68-142, 85-159, 90-190. The ordinate is a time scale, in Myr based on palaeontological views concerning the ancestral separations of the organisms from which the globins came.

nucleotide replacements in these underrepresented regions by an augmentation procedure⁵⁷ based on the distribution of nucleotide replacements in densely sequenced regions. The results obtained by our algorithm are highly correlated with results obtained by the stochastic method using Poisson distribution^{64,65} for estimating hidden mutational change in codons (G W M, M G, and R Holmquist unpublished).

Myoglobin-haemoglobin separation

In the genealogy and alignments found earlier⁶⁶ the line from the ancestral metazoan globin to the vertebrate β-α haemoglobin ancestor gave off in succession annelid, insect, mollusc, lamprey and mammalian myoglobin branches. Its length was 1,636 nucleotide replacements. Our current genealogy (Fig 1) with its corresponding alignments requires 1,629 replacements. It joins annelid and insect branches, but otherwise retains the same topology. The ancestral separation between mammalian myoglobin and β-α haemoglobin branches still occurs after the lamprey separation. To change the position of the mammalian myoglobin branch costs too many additional mutations. (The aligned sequences of the 55 contemporary globins and the reconstructed codons for these sequences as well as for the 53 ancestral nodes may be obtained by request to the authors.)

Non-uniform globin evolution

The numbers on the links in Fig 1 are the nucleotide replacement values separating adjacent ancestral and descendant sequences. Replacement values corrected for superimposed mutations are italicised. These values were used in Table 2 for calculating the rates of globin evolution during different evolutionary periods. The estimated time scale is based on palaeontological views⁶⁷⁻⁷⁰, some of which have to be considered educated guesses. Perhaps the most uncertainty pertains

to the points for the lamprey-vertebrate and invertebrate-vertebrate dichotomies. The times chosen of 500 Myr ago for the former and 680 Myr ago for the latter are more ancient than actually documented in the fossil record. These dichotomies are, however, not less than 420 and 540 Myr old respectively⁷¹. By the same token, the fossil record of the late Precambrian, while revealing unicellular organisms in abundance, provides no hint of multicellular life until very close to the end of this epoch⁷²⁻⁷⁴. Thus the ancestral separation of invertebrates (molluscs, insects, annelids) and chordates was not likely to have been earlier than 650-700 Myr ago, and it could have been somewhat later.

On *a priori* grounds⁷⁵⁻⁷⁹ and from results of Table 2, we think that rapid rates followed by slow rates occurred in globin evolution—first, when selection shaped the prototypic globin, then when new functions emerged in members of the globin family. The most ancestral portion of the reconstructed genealogy is too sparsely populated to test this hypothesis adequately. Thus Table 2 starts from the invertebrate-vertebrate ancestor at 680 Myr ago, and focuses on the vertebrates. The encompass the denser region of the genealogy and are more readily dated by palaeontological evidence. Rates are 1 nucleotide replacements per 100 codons per 10⁸ yr (NR%). During the span from the late Precambrian to the present, the globin genes evolved at an average rate of 31 NR%. This is more than three times faster than the rates found in studies^{78,80,81} in which distances between the contemporary sequence were not corrected sufficiently for superimposed mutation. Moreover, in contradistinction to conclusions⁸² on constancy of evolutionary rates, the haemoglobin genes evolved at markedly non-constant rates. For the first 380 or so Myr from the invertebrate-vertebrate to the amniote (chicken-mammal) ancestor, the haemoglobin genes evolved at an average rate of 46 NR%, but for the next 300 Myr from the amniote

ancestor to the present they evolved at the average rate of only 15 NR%. Comparable values for the unaugmented lengths are 25 NR% in the earlier period and 11 NR% in the later period. This difference is supported by a χ^2 analysis, which uses the above time estimates and the uniform rate assumption as the null hypothesis (augmented $\chi^2 = 347.3043$, $P < 0.001$, 1 d.f., unaugmented $\chi^2 = 102.8298$, $P < 0.001$, 1 d.f.). Non-uniform globin evolution has also been observed by others⁸³.

As Table 2 shows, globin evolution accelerated in the early vertebrates. This acceleration correlates with gene duplications, which first separated the vertebrate myoglobin and haemoglobin branches and then subdivided the haemoglobin branch into α and β lineages. From 500 to 400 Myr ago the genes descending from the basal vertebrate ancestor through the haemoglobin-myoglobin and β - α ancestors to the teleost-tetrapod α ancestor evolved at the rate of 109 NR%. For the following 100 Myr between the teleost-tetrapod and amniote ancestors, the rate of α evolution slowed to 36 NR%, and then over the next 300 Myr (to the present) to an average rate of 14.5 NR%. When the vertebrate haemoglobin genes are traced from the 500 Myr old vertebrate ancestor to the tetrapod β ancestor of about 340 Myr ago, the rate of nucleotide replacements comes out to 66 NR%. As the rate was 109 NR% for the genes traced to the 400 Myr old teleost-tetrapod α ancestor,

β genes at first must have evolved less rapidly than α genes. Between the tetrapod and amniote β ancestors, the β rate accelerated to 74 NR%, but then β evolution, like α evolution, abruptly slowed. The different lines of β descent from the amniote ancestor to the present evolved at an average rate of only 16 NR%.

Selectionist interpretation

We interpret the initial acceleration-eventual deceleration pattern in protein evolution this way. When mutations first produce a potentially useful protein, the possibilities for improvements are considerable. Thus mutations in the gene coding for the protein will often be advantageous and selected for, but after the protein has been perfected, a much larger proportion of mutations would be detrimental and selected against. Once many proteins have become optimised, that is more intricately coadapted for the cooperative execution of their functions, macromolecular evolution would slow. Such a pattern, however, could be temporarily interrupted by periods of accelerated evolution. This happened in early vertebrates. Mutations were selected in duplicated genes which multiplied the number of proteins with differentiated functions. Accelerated change occurred while selection was optimising the structures of these new proteins, but eventually the stabilising component of selection slowed the further rate of change.

Table 1 Residue positions with defined functional roles in mammalian α and β haemoglobin chains

We assume that homotetramers preceded heterotetramers in haemoglobin evolution. This would explain why the amino acids involved in interchain contacts occur in α and β chains mostly at homologous residue positions (Table 1). We assume further that the ancestral homotetramer had subunits more β -like in polymer forming properties than α -like, because homotetramers are readily formed by β chains but not by α ^{84,85}. Many invertebrate haemoglobins are monomers. Lamprey haemoglobin chains in the oxygenated state are also monomers. But in the deoxy state, they form homodimers⁸⁶ and transitory tetramers⁸⁷. Thus a haemoglobin more complicated than a simple monomer probably existed in the earliest vertebrates, as lampreys belong to the most primitive vertebrate class. This first vertebrate haemoglobin, if it behaved like lamprey haemoglobin, released oxygen from its haem iron atoms more readily at reduced pH and in its aggregated state. It would have been, therefore, a more useful protein than the homotetramers of β chains which lack even the rudiments of cooperativity^{84,85}. Natural selection could then exploit the possibilities for bringing about a haemoglobin more efficient at delivering oxygen to the tissues of larger-bodied, fast-moving animals. This required the evolution of heterotetrameric haemoglobin.

After the β - α gene duplication in a common ancestor of teleosts and tetrapods, positive Darwinian selection acted on the nascent α locus while stabilising selection was stronger at the β locus. Once the older β_4 type homotetramer was, however, replaced by the heterotetramer with a specialised α chain, positive selection for a more differentiated β chain intensified. This caused the rate of β evolution to accelerate between the tetrapod and amniote ancestors. Functionally superior tetrameric haemoglobin emerged. Then α and β loci were both subjected to intense stabilising selection. Evidence for this selectionist interpretation is provided by the following more detailed analysis.

Positive selection for improved function

The residue positions in Table 1 are arranged according to their functions in present day mammalian α and β chains. The positions with the most crucial functions are first the haem contacts and second those concerned with the interchain

cooperativity which facilitates oxygen delivery, the $\alpha_1\beta_2$ contacts and the salt-bridge-forming sites associated with the Bohr effect, respectively. There are many nucleotide replacements between the mollusc-vertebrate globin and amniote α and β ancestors (Table 3) at these positions, but almost no changes in the amniotes (Tables 4 and 5).

Table 3 shows the replacement values from the invertebrate-vertebrate ancestor through the basal vertebrate and the myoglobin-haemoglobin and β - α ancestors to the basal amniote α and β sequences. The most slowly evolving positions are those which now function in both α and β haemoglobin chains as haem contacts, and which must have been well established as such as far back as 600–700 Myr ago. Yet these haem contacts, although conservative compared with other residue positions, show a seven times faster evolutionary rate in the preamniotes than in the amniotes (compare Tables 3, 4, and 5). Presumably, haem-haem cooperative interactions were not fully perfected until about 300 Myr ago.

Positive Darwinian selection in the emerging vertebrates is indicated by the high proportion of changes at positions which now function as $\alpha_1\beta_2$ contacts in both α and β chains. These contacts favour haem-haem interactions by placing the haems of the contacting chains in close proximity. Positions which acquired this function evolved four times faster than the average rate over all positions (Table 3). Mutations occurred at C5, C6, FG4, G1 and HC2, five of the nine positions which now function in both α and β chains as $\alpha_1\beta_2$ contacts, as well as at FG3, a haem contact which also functions as an $\alpha_1\beta_2$ contact in amniote α chains. The mutations of glutamic acid (GAG) to glutamine (CAG) at C5, valine (GUG) to glutamine (CAG) at FG4, asparagine (AAU) to aspartic acid (GAU) at G1, isoleucine (AUU) to tyrosine (UAU) at HC2, and arginine (CGU) to leucine (CUU) at FG3 persisted. They are central to the interchain cooperativity of present-day tetrameric haemoglobin.

Between the myoglobin-haemoglobin and β - α ancestors, the sites which now function as $\alpha_1\beta_1$ contacts in both α and β chains evolved at twice the average rate of all positions (Table 3). Lysine (AAA) mutated to isoleucine (AUA) at B15, aspartic acid (GAU) to asparagine (AAU) at G10, aspartic acid (GAU)

Table 2 Rates of mollusc and vertebrate globin evolution

Evolutionary period	Age (Myr BP) Mollusc, agnathan, and jawed vertebrate globins	Nucleotide replacements per 100 codons per 10 ⁸ yr
Invertebrate-vertebrate ancestor to <i>Aplysia</i> 'myoglobin'	680– 0	16.1
Invertebrate-vertebrate ancestor to vertebrate globins	680– 0	31.2 (20.5–35.3)
Invertebrate-vertebrate to vertebrate ancestor	680–500	19.5
Vertebrate ancestor to lamprey globins	500– 0	21.0 (20.9–21.0)
Vertebrate ancestor to myoglobins	500– 0	31.6 (29.6–33.2)
Vertebrate ancestor to α_s and β_s	500– 0	37.1 (33.5–40.9)
Vertebrate to therian myoglobin ancestor	500–120	36.2
Therian myoglobin ancestor to myoglobins	120– 0	17.2 (8.7–23.4)
Vertebrate to tetrapod β ancestor	500–340	65.7
Tetrapod β ancestor to β_s	340– 0	22.9 (18.3–28.4)
Vertebrate to teleost-tetrapod α ancestor	500–400	108.9
Teleost-tetrapod α ancestor to α_s	400– 0	19.9 (18.1–23.9)
α Lineage		
Teleost-tetrapod ancestor to teleost α_s	400– 0	18.7 (18.1–19.3)
Teleost-tetrapod ancestor to amniote α_s	400– 0	20.0 (18.6–23.9)
Teleost-tetrapod to amniote α ancestor	400–300	36.2
Amniote ancestor to chicken α	300– 0	12.1
Amniote ancestor to mammalian α_s	300– 0	14.7 (12.5–19.9)
Amniote to eutherian α ancestor	300–90	12.5
Eutherian ancestor to human α	90– 0	13.4
Eutherian ancestor to all eutherian α_s	90– 0	18.5 (12.6–37.0)
β Lineage		
Tetrapod ancestor to frog β	340– 0	24.2
Tetrapod ancestor to amniote β_s	340– 0	22.8 (18.3–28.4)
Tetrapod to amniote β ancestor	340–300	73.6
Amniote ancestor to chicken β	300– 0	12.3
Amniote ancestor to mammalian β_s	300– 0	16.3 (12.3–22.3)
Amniote to eutherian β ancestor	300–90	10.8
Eutherian ancestor to human β	90– 0	16.7
Eutherian ancestor to all eutherian β_s	90– 0	26.6 (11.4–49.4)

Table 3 Nucleotide replacement lengths for groups of residue positions

Type of residue positions	During emergence of hypothetical homopolymer						During evolution of nascent heterotetramer			
	Invert-vert to vert anc		Vert to myo-Hb anc		Myo-Hb to β - α anc		β - α to amniote α anc		β - α to amniote β anc	
	No of positions	Average length	No of positions	Average length	No of positions	Average length	No of positions	Average length	No of positions	Average length
Haem contacts in both β and α and in myoglobin chains	18	0.11	18	0.17	18	0.06	18	0.17	18	0.11
Non-haem $\alpha_1\beta_2$ contacts in both β and α chains	9	0.78	9	0.00	9	0.22	9	0.67	9	0.44
Like-chain contacts in both β and α chains	3	0.00	3	0.00	3	0.00	3	0.33	3	0.67
$\alpha_1\beta_1$ contacts in both β and α chains	13	0.23	13	0.23	13	0.38	13	0.31	13	0.31
With defined functions in α but not β chains	7	0.14	7	0.14	7	0.29	7	0.86	7	0.14
With defined functions in β but not α chains	12	0.33	12	0.08	12	0.17	9	0.11	12	0.67
Remaining interior positions	19	0.16	19	0.26	19	0.05	18	0.22	19	0.26
Remaining exterior positions	67	0.13	67	0.21	67	0.31	64.5	0.48	65	0.28
All positions	148	0.20	148	0.18	148	0.23	141.5	0.40	146	0.30

Positions are grouped according to their functional roles in present-day haemoglobin chains, as may be identified from Table 1, unaugmented nucleotide replacements for the positions in each group during each period of descent are averaged. B12, C1, H5, and H9 are included in the group consisting of $\alpha_1\beta_1$ contacts in both β and α chains since the emergence of this function probably preceded the emergence of their Bohr-effect-related function. The seven positions with defined functions in α but not β chains are A4, B11, CD2, G6, G11, G13, and H12.

The twelve positions with defined functions in β but not α chains are NA2, D2, D6, E10, E14, E15, EF6, FG1, G17, H1, H3 and H21.

to valine (GUU) at G14, alanine (GCG) to proline (CCG) at GH2, and also alanine (GCU) to proline (CCU) at H2. Then these amino acids, along with those at other prospective $\alpha_1\beta_1$ contact sites, either persisted or mutated to similar amino acids in later amniote haemoglobin chains. This supports the notion that the β - α gene was coding for homotetrameric haemoglobin even before it duplicated. Conversely in the myoglobin lineage, tyrosine mutated to histidine, tyrosine to lysine, leucine to histidine, aspartic acid to proline, proline to valine, and glutamic acid to lysine at C1, C7, FG3, G1, G2, and H9, respectively. These mutations at positions which function as interchain contacts in haemoglobin polymers helped reshape the myoglobin molecule into a high oxygen affinity monomer.

The positions which are $\alpha_1\beta_2$ contacts in the two haemoglobin chain types evolved at a faster than average rate in the nascent α and β lineages (Table 3). Also the positions categorised as like-chain contacts in both α and β chains evolved at a faster than average rate because of mutations at HC3, a Bohr effect site in both α and β chains, as well as an $\alpha_1\beta_2$ contact site in β chains. (Ancestral lysine (AAG) mutated to arginine (AGG) at α HC3 and to histidine (CAU) at β HC3). Positions which acquired important functions in α chains but not in β evolved in the α lineage at a faster rate than other positions. Similarly, positions which acquired important functions in β chains but not in α evolved in the β lineage at a faster rate than other positions.

The evidence in Table 3 for positive selection directing the evolution of early vertebrate haemoglobin is supported by a χ^2 test, performed to test the null hypothesis that sites where mutations produced acquired crucial functions did not evolve at a different rate from all other sites. Homopolymer emergence was tested by comparing nucleotide replacements at prospective $\alpha_1\beta_2$ and $\alpha_1\beta_1$ contact positions with all other positions in the invertebrate-vertebrate to vertebrate and myoglobin-haemoglobin to β - α ancestors ($\chi^2 = 7.312$, $P < 0.01$, 1 d.f.). Heterotetramer evolution was tested by comparing nucleotide replacements at $\alpha_1\beta_2$ contacts, like-chain contacts, and α -only functions in the β - α to amniote α lineage, plus $\alpha_1\beta_2$ contacts, like-chain contacts, and β -only functions in the β - α to amniote β lineage, with the other positions ($\chi^2 = 11.403$, $P < 0.001$, 1 d.f.).

Mutations were fixed in the diverging α and β genes because they produced functionally superior haemoglobin molecules. By the time amniote tetrapods evolved, heterotetramers with modern allosteric properties had replaced the older models.

Thereafter natural selection acted against further amino acid substitutions at the residue positions involved in haem and $\alpha_1\beta_2$ contacts and the Bohr effect. Nucleotide replacements occurred in the codons for these positions at only one-fifth to one-tenth the average rate (Tables 4 and 5). Moreover, the average rate itself was much reduced.

Darwinian selection, however, was still directing haemoglobin evolution. This is demonstrated by nucleotide replacements at 2,3-diphosphoglycerate (DPG)-binding sites. For example, between the amniote and mammal (protherian and therian) β ancestor, glutamine (CAG) at H21 mutated to histidine (CAU). The greater binding of DPG to the β chain produced by this mutation further facilitated the unloading of oxygen from haemoglobin in the deoxy conformation^{51,53}. The effect was reversed in the line to human γ chain by H21 histidine mutating to serine. This mutation favoured the ability of foetal haemoglobin to compete with adult haemoglobin for oxygen.

Darwinian selection can also explain changes observed at positions NA2, A2, A7, CD2, D2, E2, EF5, G18, GH2 and H2 in descent from the metazoan ancestor to human α and β sequences, proline replaced alanine five times more often than alanine replaced proline. Alanines can appear anywhere in a globin chain, but prolines are restricted to sites at the end of helices or to non-helical regions where they delimit the lengths.

Table 4 Effect of functions on nucleotide replacement lengths in the amniote ancestor-to-contemporary α lineages

Type of residue positions	No of positions	Average length	Nucleotide replacements per position per 100 Myr
Haem contacts	19	0.37	0.02
Non-haem contact $\alpha_1\beta_2$ contacts	10	0.20	0.01
